CHAPTER 23

INSULATION FOR MECHANICAL SYSTEMS

Design Objectives and Considerations 23.1
Materials and Systems 23.9
Installation 23.13
Design Data 23.18
Project Specifications 23.19

THIS chapter deals with applications of thermal and acoustical insulation for mechanical systems in residential, commercial, and industrial facilities. Applications include pipes, tanks, vessels and equipment, and ducts.

Thermal insulation is primarily used to limit heat gain or loss from surfaces operating at temperatures above or below ambient temperature. Insulation may be used to satisfy one or more of the following design objectives:

- **Energy conservation**: minimizing unwanted heat loss/gain from building HVAC systems, as well as preserving natural and financial resources
- **Economic thickness**: selecting the thickness of insulation that yields the minimum total life-cycle cost
- **Personnel protection**: controlling surface temperatures to avoid contact burns (hot or cold)
- **Condensation control**: minimizing condensation by keeping surface temperature above the dew point of surrounding air
- **Process control**: minimizing temperature change in process fluids where close control is needed
- **Freeze protection**: minimizing energy required for heat tracing systems and/or extending the time to freezing in the event of system failure or when the system is purposefully idle
- **Noise control**: reducing/controlling noise in mechanical systems
- **Fire safety**: protecting critical building elements and slowing the spread of fire in buildings

Fundamentals of thermal insulation are covered in Chapter 25; applications in insulated assemblies are discussed in Chapter 27; and data on thermal and water vapor transmission data are in Chapter 26.

1. DESIGN OBJECTIVES AND CONSIDERATIONS

Energy Conservation

Thermal insulation is commonly used to reduce energy consumption of HVAC systems and equipment. Minimum insulation levels for ductwork and piping are often dictated by energy codes, many of which are based on ASHRAE *Standards* 90.1 and 90.2. In many cases, it may be cost-effective to go beyond the minimum levels dictated by energy codes. Thicknesses greater than the optimum economic thickness may be required for other technical reasons such as condensation control, personnel protection, or noise control.

Tables 1 to 3 contain minimum insulation levels for ducts and pipes, excerpted from ANSI/ASHRAE *Standard* 90.1-2010.

Interest in **green buildings** (i.e., those that are environmentally responsible and energy efficient, as well as healthier places to work) is increasing. The LEED® (Leadership in Energy and Environmental Design) Green Building Rating System™, created by the U.S. Green Building Council, is a voluntary rating system that sets out sustainable design and performance criteria for buildings. It evaluates environmental performance from a whole-building perspective and awards points based on satisfying performance criteria in several different categories. Different levels of green building certification are awarded based on the total points earned. The role of mechanical insulation in reducing energy usage, along with the associated greenhouse gas emissions, can help to contribute to LEED certification and should be considered when designing an insulation system.

Economic Thickness

Economics can be used to (1) select the optimum insulation thickness for a specific insulation, or (2) evaluate two or more insulation materials for least cost for a given level of thermal performance. In either case, economic considerations determine the most cost-effective solution for insulating over a specific period.

Life-cycle costing considers the initial cost of the insulation system plus the ongoing value of energy savings over the expected service lifetime. The economic thickness is defined as the thickness that minimizes the total life-cycle cost.

Labor and material costs of installed insulation increase with thickness. Insulation is often applied in multiple layers (1) because materials are not manufactured in single layers of sufficient thickness and (2) in many cases, to accommodate expansion and contraction of insulation and system components. Figure 1 shows installed costs for a multilayer application. The slope of the curves is discontinuous and increases with the number of layers because labor and material costs increase more rapidly as thickness increases. Figure 1 shows curves of total cost of operation, insulation costs, and lost energy costs. Point A on the total cost curve corresponds to the economic insulation

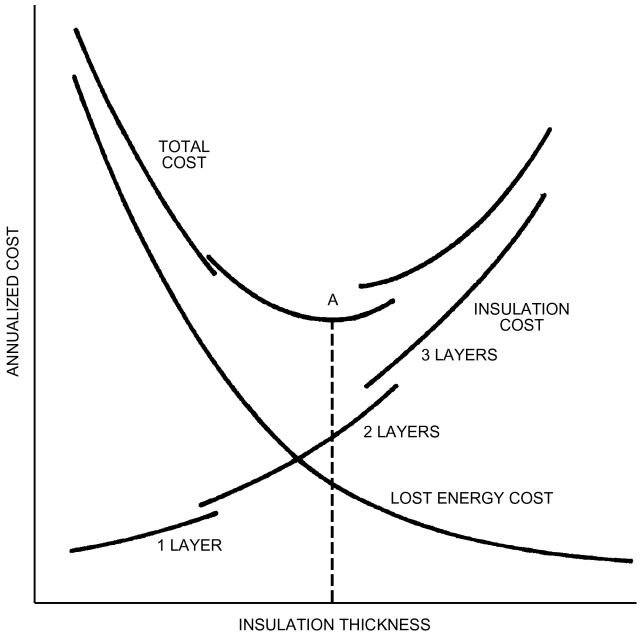

Fig. 1 Determination of Economic Thickness of Insulation

The preparation of this chapter is assigned to TC 1.8, Mechanical Systems Insulation.

<4	0.032 to 0.040	10	13	25	25	25	38

[a]For insulation outside stated conductivity range, determine minimum thickness T as follows:

$$T = r\{(1 + t/r)^{K/k} - 1\}$$

where T = minimum insulation thickness (mm), r = actual outside radius of pipe (mm), t = insulation thickness listed in this table for applicable fluid temperature and pipe size, K = conductivity of alternative material at mean rating temperature indicated for applicable fluid temperature [W/(m·K)]; and k = upper value of conductivity range listed in this table for applicable fluid temperature.
[b]These thicknesses are based on energy *efficiency* considerations only. Additional insulation is sometimes required relative to safety issues/surface temperature.
[c]Piping insulation is not required between the control valve and coil on run-outs when the control valve is located within 1.2 m of the coil and the pipe size is 25 mm or less.
[d]These thicknesses are based on energy *efficiency* considerations only. Issues such as water vapor permeability or surface condensation sometimes require vapor retarders or additional insulation.

thickness, which, in this example, is in the double-layer range. Viewing the calculated economic thickness as a minimum thickness provides a hedge against unforeseen fuel price increases and conserves energy.

Initially, as insulation is applied, the total life-cycle cost decreases because the value of incremental energy savings is greater than the incremental cost of insulation. Additional insulation reduces total cost up to a thickness where the change in total cost is equal to zero. At this point, no further reduction can be obtained; beyond it, incremental insulation costs exceed the additional energy savings derived by adding another increment of insulation.

Economic analysis should also consider the time value of money, which can be based on a desired rate of return for the insulation investment. Energy costs are volatile, and a fuel cost inflation factor is sometimes included to account for the possibility that fuel costs may increase more quickly than general inflation. Insulation system maintenance costs should also be included, along with cost savings associated with the ability to specify lower capacity equipment, resulting in lower first costs.

Chapter 37 of the 2019 *ASHRAE Handbook—HVAC Applications* has more information on economic analysis.

Personnel Protection

In many applications, insulation is provided to protect personnel from burns. The potential for burns to human skin is a complex function of surface temperature, surface material, and time of contact.

ASTM *Standard* C1055 has a good discussion of these factors. Standard industry practice is to specify a maximum temperature of 60°C for surfaces that may be contacted by personnel. For indoor applications, maximum air temperatures depend on the facility and location, and are typically lower than design outdoor conditions. For outdoor installations, base calculations on summer design ambient temperatures with no wind (i.e., the worst case). Surface temperatures increase because of solar loading, but are usually neglected because of variability in orientation, solar intensity, and many other complicating factors. Engineering judgment must be used in selecting ambient and operating temperatures and wind conditions for these calculations.

Note that the choice of jacketing strongly affects a surface's relative safety. Higher-emittance jacketing materials (e.g., plastic, painted metals) can be selected to minimize the surface temperature. Jacketing material also affects the relative safety at a given surface temperature. For example, at 80°C, a stainless steel jacket blisters skin more severely than a nonmetallic jacket at equal contact time.

Condensation Control

For below-ambient systems, condensation control is often the overriding design objective. The design problem is best addressed as two separate issues: (1) avoiding surface condensation on the outer surface of the insulation system and (2) minimizing or managing water vapor intrusion.

Avoiding surface condensation is desirable because it (1) prevents dripping, which can wet surfaces below; (2) minimizes mold growth by eliminating the liquid water many molds require; and (3) avoids staining and possible damage to exterior jacketing.

The design goal is to keep the surface temperature above the dew-point temperature of surrounding air. Calculating surface temperature is relatively simple, but selecting the appropriate design conditions is often confusing. The appropriate design condition is normally the worst-case condition expected for the application. For condensation control, however, a design that satisfies the worst case is sometimes impossible.

To illustrate, Table 4 shows insulation thicknesses required to prevent condensation on the exterior surface of a hypothetical insulated tank containing a liquid held at 4°C in a mechanical room with a temperature of 27°C. Note that, at high relative humidities, the thickness required to prevent surface condensation increases dramatically, and becomes impractical above 90% rh.

Table 4 Insulation Thickness Required to Prevent Surface Condensation

Relative Humidity, %	Thickness, mm
20	—
30	2.5
40	5.0
50	7.5
60	13
70	18
80	33
90	74
95	150

Note: Calculated using Equation (14), assuming surface conductance of 6.8 $W/(m^2 \cdot K)$ and insulation with thermal conductivity of 0.043 $W/(m \cdot K)$. Different assumed values yield different results.

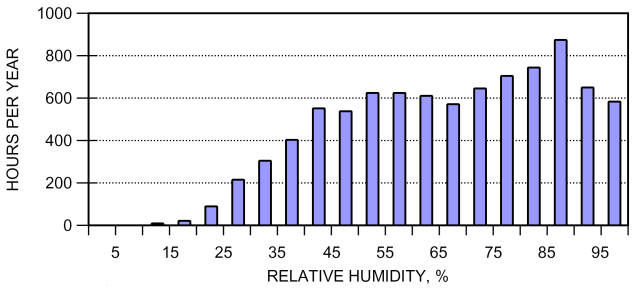

Fig. 2 Relative Humidity Histogram for Charlotte, NC

For outdoor applications (or for unconditioned spaces vented to outdoor air), there are always some hours per year where the ambient air is saturated or nearly saturated. For these times, no amount of insulation will prevent surface condensation. Figure 2 shows the frequency distribution of outdoor relative humidity based on typical meteorological year weather data for Charlotte, North Carolina (Marion and Urban 1995). Note that there are over 1200 h per year when the relative humidity is equal to or greater than 90%, and nearly 600 h per year when the relative humidity is equal to or greater than 95%.

For outdoor applications and mechanical rooms vented to outdoor conditions, it is suggested to design for a relative humidity of

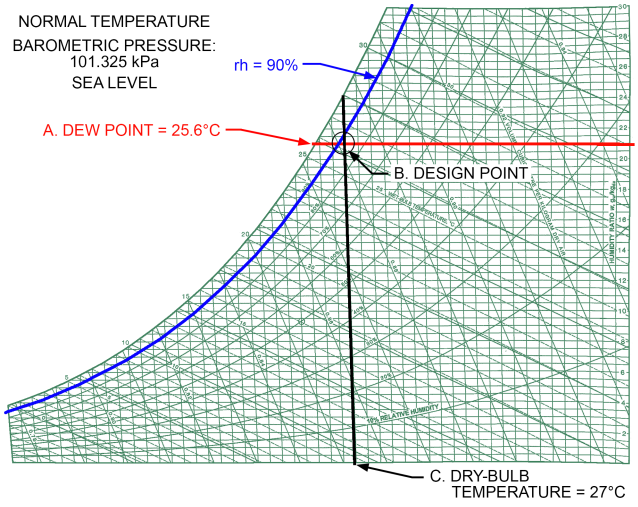

Fig. 3 ASHRAE Psychrometric Chart No. 1

90%. Appropriate water-resistant vapor-retarder jacketing or mastics must then be specified to protect the system from the inevitable surface condensation.

Table 5 summarizes design weather data for a select number of cities. The design dew-point temperature and the corresponding dry-bulb temperatures at 90% rh are given, along with the number of hours per year that the relative humidity would exceed 90%. Additional design dew-point data can be found in Chapter 14.

Design Example: Tampa, Florida.

Chilled-water supply piping is to be located outdoors to serve a commercial building expansion in Tampa, Florida. The supply piping is 150 mm NPS steel and the design temperature of the chilled-water supply is 4.4°C. Determine the appropriate design ambient conditions for this installation. From Table 5, the design dew-point temperature for Tampa is 25.6°C.

The design conditions are best visualized using a psychrometric chart, which graphically represents the properties of moist air. The horizontal axis is dry-bulb temperature, and the vertical axis is humidity ratio (kg of water vapor per kg of dry air). The chart includes the saturation curve (relative humidity = 100%) as well as parallel curves for other values of constant relative humidity. Lines of constant dew-point temperature are horizontal on the psychrometric chart.

Using Figure 3, enter the chart on the saturation curve at a dew point of 25.6°C (point A. in the figure) and draw a horizontal line. The design point is located where this horizontal line intersects the 90% rh curve. The dry-bulb temperature associated with this design point is read from the horizontal axis at point C, which for this example is approximately 27°C. The insulation system should therefore be designed for an operating temperature of 4.4°C, an ambient temperature of 27°C, and an ambient relative humidity of 90%.

This section is based on WDBG (2012).

For indoor designs in conditioned spaces, care is needed when selecting design conditions. Often, the HVAC system is sized to provide indoor conditions of 24°C/50% rh on a design summer day. However, those indoor conditions do not represent the worst-case indoor conditions for insulation design. Part-load conditions could result in higher humidity levels, or night and/or weekend shutdown could result in more severe conditions.

In addition to avoiding condensation on the exposed surface, another important design consideration is minimizing or managing water vapor intrusion, which is extremely important for piping and equipment operating at below-ambient temperatures. Water-related problems include thermal performance loss, health and safety issues, structural degradation, and aesthetic issues. Water entry into

the insulation system may be through diffusion of water vapor, air leakage carrying water vapor, and leakage of surface water.

When the operating temperature is below the dew point of the surrounding ambient air, there is a difference in water vapor pressure across the insulation system. This vapor-pressure difference drives diffusion of water vapor from the ambient toward the cold surface. Piping and equipment typically create an absolute barrier to the passage of water vapor, so any vapor-pressure difference imposed across the insulation system results in the potential for condensation either in the insulation or at the cold surface. The vapor-pressure difference can range from below 345 Pa for a supply air duct operating in the return air plenum of a commercial building, to over 4 kPa for a cryogenic system operating outdoors near the U.S. Gulf Coast. Although these pressure differences seem small, the effect over many operating hours can be significant.

Several fundamental design principles are used in managing water vapor intrusion. One method is to reduce the driving force by reducing the moisture content of the surrounding air. The insulation designer typically does not have control of the location of the piping, ductwork, or equipment to be insulated, but there are opportunities for the mechanical engineer to influence ambient conditions. Certainly, locating cold piping, ductwork, and equipment in unconditioned portions of buildings should be minimized. Consider conditioning mechanical rooms if feasible.

Another common method is moisture blocking, wherein passage of water vapor is eliminated or minimized to an insignificant level. The design must incorporate the following: (1) a vapor retarder with suitably low permeance; (2) a joint and seam sealing system that maintains vapor retarding system integrity; and (3) accommodation for future damage repair, joint and seam resealing, and reclosing after maintenance.

A vapor retarder is a material or system that adequately reduces transmission of water vapor through the insulation system. The vapor retarder system is seldom intended to resist entry of surface water or prevent air leakage, but can occasionally be considered the second line of defense for these moisture sources.

An effective vapor retarder material or system is essential for blocking systems to perform adequately. Mumaw (2001) showed that the design, installation, and performance of vapor retarder systems are key to the ability of an insulation system to minimize water vapor ingress. Performance of the vapor retarder material or system is characterized by the water vapor permeance: the lower the permeance, the better. The water vapor permeance can be evaluated using procedures outlined in ASTM *Standard* E96. In this test, a vapor pressure difference is imposed across vapor retarder material that has been sealed to a test cup, and the moisture gain or loss is measured gravimetrically.

The insulation system should be dry before applying a vapor retarder to prevent trapping water vapor in the insulation system.

Licensed for single user. © 2021 ASHRAE, Inc.

The insulation system also must be protected from undue weather exposure that could introduce moisture into the insulation before the system is sealed.

Faulty application techniques can impair vapor retarder performance. The effectiveness of installation and application techniques must be considered during selection. Factors such as vapor retarder structure, number of joints, mastics and adhesives that are used, as well as inspection procedures affect system performance and durability.

When selecting a vapor retarder, the vapor-pressure difference across the insulation system should be considered. Higher vapor-pressure differences typically require a vapor retarder with a lower permeance to control the overall moisture pickup of the insulated system. Service conditions affect the direction and magnitude of the vapor pressure difference: unidirectional flow exists when the water vapor pressure is constantly higher on one side of insulation system, whereas reversible flow exists when vapor pressure may be higher on either side (typically caused by diurnal or seasonal changes on one side of the insulation system). Properties of the insulation system materials should be considered. All materials reduce the flow of water vapor; the low permeance of some insulation materials can add to the overall resistance to water vapor transport of the insulation system. All vapor retarder joints should be tightly sealed with manufacturer-recommended sealants.

Another fundamental design principle is moisture storage design. In many systems, some condensation can be tolerated, the amount depending on the water-holding capacity or tolerance of a particular system. The moisture storage principle allows accumulation of water in the insulation system, but at a rate designed to prevent harmful effects. This concept is applicable when (1) unidirectional vapor flow occurs, but accumulations during severe conditions can be adequately expelled during less severe conditions; or (2) reverse flow regularly occurs on a seasonal or diurnal cycle. Design solutions using this principle include (1) periodically flushing the cold side with low-dew-point air (requires a supply of conditioned air and a means for distribution), and (2) using an insulation system supplemented by selected vapor retarders and absorbent materials such that an accumulation of condensation is of little importance. Such a design must ensure sufficient expulsion of accumulated moisture.

ASTM *Standard* C755 discusses various design principles. Chapters 25 to 27 of this volume thoroughly describe the physics associated with water vapor transport. Additional information is found in Chapter 10 of the 2018 *ASHRAE Handbook—Refrigeration*, and in ASTM (2001).

Freeze Prevention

It is important to recognize that insulation retards heat flow; it does not stop it completely. If the surrounding air temperature remains low enough for an extended period, insulation cannot prevent freezing of still water or of water flowing at a rate insufficient for the available heat content to offset heat loss. Insulation can prolong the time required for freezing, or prevent freezing if flow is maintained at a sufficient rate. To calculate time θ (in hours) required for water to cool to 0°C with no flow, use the following equation:

$$\theta = (1/3600)\rho C_p \pi (D_1/2)^2 R_T \ln[(t_i - t_a)/(t_f - t_a)] \quad (1)$$

where

θ = time to freezing, h
ρ = density of water = 1000 kg/m^3
C_p = specific heat of water = 4200 J/(kg·K)
D_1 = inside diameter of pipe, m (see Figure 4)
R_T = combined thermal resistance of pipe wall, insulation, and exterior air film (for a unit length of pipe)
t_i = initial water temperature, °C
t_a = ambient air temperature, °C

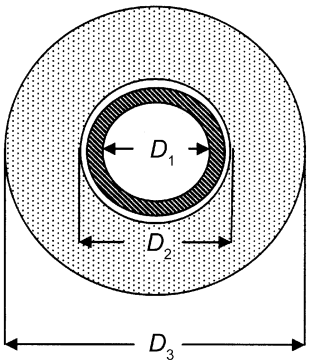

Fig. 4 Time to Freeze Nomenclature

Table 6 Time to Cool Water to Freezing, h

Nominal Pipe Size, mm	Insulation Thickness, mm					
	13	25	38	50	75	100
15	0.1	0.2	0.2	0.3	—	—
25	0.3	0.4	0.5	0.6	0.8	—
40	0.4	0.8	1.0	1.3	1.5	—
50	0.6	1.1	1.4	1.7	2.2	2.5
80	0.9	1.7	2.3	2.9	3.7	4.5
100	1.3	2.4	3.3	4.1	5.5	6.6
125	1.6	3.0	4.3	5.4	7.4	9.1
150	1.9	3.7	5.3	6.9	9.4	11.7
200	—	5.3	7.6	9.6	13.7	16.9
250	—	6.5	10.2	12.9	17.9	22.3
300	—	8.8	12.5	15.8	22.1	27.7

Note: Assumes initial temperature = 5.5°C, ambient air temperature = –28°C, and insulation thermal conductivity = 0.0432 W/(m·K). Thermal resistances of pipe and air film are neglected. Different assumed values yield different results.

t_f = freezing temperature, °C

As a conservative assumption for insulated pipes, thermal resistances of pipe walls and exterior air film are usually neglected. Resistance of the insulation layer for a unit length of pipe is calculated as

$$R_T = \ln(D_3/D_2)/(2\pi k) \quad (2)$$

where

D_3 = outer diameter of insulation, m
D_2 = inner diameter of insulation, m
k = thermal conductivity of insulation material, W/(m·K)

Table 6 shows estimated time to freezing, calculated using these equations for the specific case of still water with t_i = 6°C and t_a = –28°C.

When unusual conditions make it impractical to maintain protection with insulation or flow, a hot trace pipe or electric resistance heating cable is required along the bottom or top of the water pipe. The heating system then supplies the heat lost through the insulation.

Clean water in pipes usually supercools several degrees below freezing before any ice is formed. Then, upon nucleation, dendritic ice forms in the water and the temperature rises to freezing. Ice can be formed from water only by the release of the latent heat of fusion (335 kJ/kg) through the pipe insulation. Well-insulated pipes may greatly retard this release of latent heat. Gordon (1996) showed that water pipes burst not because of ice crystal growth in the pipe, but because of elevated fluid pressure within a confined pipe section occluded by a growing ice blockage.

Noise Control

Duct Insulation. Without insulation, the acoustical environment of mechanically conditioned buildings can be greatly compromised, resulting in reduced productivity and a decrease in occupant comfort. HVAC ducts act as conduits for mechanical equipment noise, and also carry office noise between occupied spaces. Additionally, some ducts can create their own noise through duct wall vibrations or expansion and contraction. Lined sheet metal ducts and fibrous glass rigid ducts can greatly reduce transmission of HVAC noise through the duct system. The insulation also reduces cross-talk from one room to another through the ducts. A good discussion of duct acoustics is provided in Chapter 48 of the 2019 *ASHRAE Handbook—HVAC Applications*. Duct insulation can be used to provide both attenuation loss and breakout noise reduction.

Attenuation loss is noise absorbed within the duct. In uninsulated ducts, it is a function of duct geometry and dimensions as well as noise frequency. Internal insulation liners are generally available for most duct geometries. Chapter 48 in the 2019 *ASHRAE Handbook—HVAC Applications* provides attenuation losses for square, rectangular, and round ducts lined with fibrous glass, and also gives guidance on use of insulation in plenums to absorb duct system noise. Internal linings can be very effective in fittings such as elbows, which can have 2 to 8 times more attenuation than an unlined elbow of the same size. For alternative lining materials, consult individual manufacturers.

It is difficult to write specifications for sound attenuation because it changes with every duct dimension and configuration. Thus, insulation materials are generally selected for attenuation based on sound absorption ratings. Sound absorption tests are run per ASTM *Standard* C423 in large reverberation rooms with random sound incidence. The test specimens are laid on the chamber floor per ASTM *Standard* E795, type A mounting. This mode of sound exposure is different from the exposure of internal linings installed in an air duct; therefore, sound absorption ratings for materials can only be used for general comparisons of effectiveness when used in air ducts of varying dimensions (Kuntz and Hoover 1987).

Breakout noise is from vibration of the duct wall caused by air pressure fluctuations in the duct. Absorptive insulation can be used in combination with mass-loaded jacketing materials or mastics on the duct exterior to reduce breakout noise. This technique is only minimally effective on rectangular ducts, which require the insulation and mass composite to be physically separated from the duct wall to be very effective. For round ducts, as with pipes, absorptive insulation and mass composite can be effective even when directly applied to the duct surface. Chapter 48 in the 2019 *ASHRAE Handbook—HVAC Applications* provides breakout noise guidance data.

Noise Radiating from Pipes. Noise from piping can be reduced by adding an absorptive insulation and jacketing material. By knowing the sound insertion loss of insulation and jacketing material combinations, the expected level of noise reduction in the field can be estimated. A range of jacket weights and insulation thicknesses can be used to reduce noise. Jackets used to reduce noise are typically referred to as being mass filled. Some products for outdoor applications use mass-filled vinyl (MFV) in combination with aluminum.

Pipe insertion loss is a measurement (in dB) of the reduction in sound pressure level from a pipe as a result of application of insulation and jacketing. Measured at different frequencies, the noise level from the jacketed pipe is subtracted from that of the bare pipe; the larger the insertion loss number, the larger the amount of noise reduction.

ASTM *Standard* E1222 describes how to determine insertion loss of pipe jacketing systems. A band-limited white noise test signal is produced inside a steel pipe located in a reverberation room, using a loudspeaker or acoustic driver at one end of the pipe to produce the noise. Average sound pressure levels are measured in the room for two conditions: with sound radiating from a bare pipe, and with the same pipe covered with a jacketing system. The insertion loss of the jacketing system is the difference in the sound pressure levels measured, adjusted for changes in room absorption caused by the jacketing system's presence. Results may be obtained in a series of 100 Hz wide bands or in one-third octave bands from 500 to 5000 Hz.

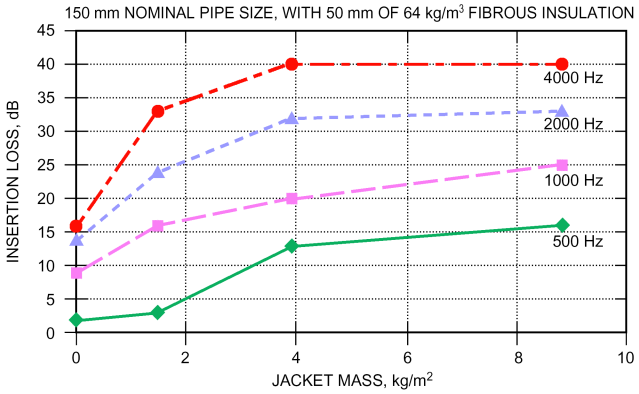

Fig. 5 Insertion Loss Versus Mass of Jacket

Table 7 gives measured insertion loss values for several pipe insulation and jacket combinations. The mass of the jacket material significantly affects insertion loss of pipe insulation systems. Figure 5 represents insertion loss of typical fibrous pipe insulations with various weights of jacketing (Miller 2001).

It is very important that sound sources be well identified in industrial settings. It is possible to treat a noisy pipe very effectively and have no significant influence on ambient sound measurement after treatment. All sources of noise above desired levels must receive acoustical treatment, beginning with the largest source, or no improvement will be observed.

Fire Safety

Materials used to insulate mechanical equipment generally must meet the requirements of local codes adopted by governmental entities having jurisdiction over the project. In the United States, most local codes incorporate or are patterned after model codes developed and maintained by organizations such as the National Fire Protection Association (NFPA) and International Code Council (International Codes). Refer to local codes to determine specific requirements.

Most codes related to insulation product fire safety refer to the surface burning characteristics as determined by the Steiner tunnel test (ASTM *Standard* E84, UL *Standard* 723, or CAN/ULC *Standard* S-102). These similar test methods evaluate the flame spread and smoke developed from samples mounted in a 7.62 m long tunnel and subsequently exposed to a controlled flame. Results are given in terms of *flame spread* and *smoke developed* indices, which are relative to a baseline index and calibration standards of inorganic reinforced cement board (0) and select-grade red oak flooring (100). Samples are normally mounted with the exposed surface face down in the ceiling of the tunnel. Upon ignition, the progress of the flame front is timed while being tracked visually for distance down the tunnel, with the results used to calculate the flame spread index. Smoke index is determined by measuring smoke density with a light cell mounted in the exhaust stream.

Using supporting materials on the underside of the test specimen can lower the flame spread index. Materials that melt, drip, or delaminate to such a degree that the continuity of the flame front is destroyed give low flame spread indices that do not relate directly to indices obtained by testing materials that remain in place. Alternative

means of testing may be necessary to fully evaluate some of these materials.

For pipe and duct insulation products, samples are prepared and mounted in the tunnel per ASTM *Standard* E2231, which directs that "the material, system, composite, or assembly tested shall be representative of the completed insulation system used in actual field installations, in terms of the components, including their respective thicknesses." Samples are constructed to mimic, as closely as possible, the products as they will be used, including any facings and adhesives as appropriate.

Duct insulation generally requires a flame spread index of not more than 25 and a smoke developed index of not more than 50, when tested in accordance with ASTM *Standard* E84. Codes often require factory-made duct insulations (e.g., insulated flexible ducts, rigid fibrous glass ducts) to be listed and labeled per UL *Standard* 181. This standard specifies several other fire tests (e.g., flame penetration and low-energy ignition) as part of the listing requirements.

Some building codes require that duct insulations meet the fire hazard requirements of NFPA *Standard* 90A or 90B, to restrict spread of smoke, heat, and fire through duct systems, and to minimize ignition sources. Local code authorities should also be consulted for specific requirements.

For pipe insulation, the requirement is generally a maximum flame spread index of 25 and a maximum smoke developed index of 450 in nonplenum spaces (in plenums, less than or equal to 25 and 50, respectively). Consult local code authorities for specific requirements.

The term *noncombustible*, as defined by building codes, refers to materials that pass the requirements of ASTM *Standard* E136. This test method involves introducing a small specimen of the material into a furnace initially maintained at a temperature of 750°C. The temperature rise of the furnace is monitored and the specimen is observed for any flaming. Criteria for passing include limits on temperature rise, flaming, and weight loss of the specimen. Some building codes accept as noncombustible a composite material having a structural base of noncombustible material and a surfacing not more than 3 mm thick that has a flame spread index not greater than 50. A related term sometimes referenced in building codes is *limited combustible*, which is an intermediate category that considers the potential heat content of materials determined per the testing requirements of NFPA *Standard* 259.

Mechanical insulation materials are often used as a component in systems or assemblies designed to protect buildings and equipment from the effects or spread of fire (i.e., **fire-resistance assemblies**). They can include walls, roofs, floors, columns, beams, partitions, joints, and through-penetration fire stops. Specific designs are tested and assigned hourly ratings based on performance in full-scale fire tests. Note that insulation materials alone are not assigned hourly fire resistance ratings; ratings are assigned to a system or assembly that may include specific insulation products, along with other elements such as framing members, fasteners, wallboard, etc.

Fire resistance ratings are often developed using ASTM *Standard* E119. This test exposes assemblies (walls, partitions, floor or roof assemblies, and through-penetration fire stops) to a standard fire exposure controlled to achieve specified temperatures throughout a specified time period. The time/temperature curve is intended to represent building fires where the primary fuel is solid, and specifies a temperature of 540°C at 5 min, 930°C at 1 h, and 1260°C at 8 h. In the hydrocarbon processing industry, liquid hydrocarbon-fueled pool fires are a concern; fire resistance ratings for these applications are tested per ASTM *Standard* E1529. This time/temperature curve rises rapidly to 1090°C within 5 min, and remains there for the duration of the test.

Fire-resistant rated designs can be found in the directories of listing agencies. Examples of such agencies include Underwriters Laboratories, Factory Mutual, UL Canada, and Intertek.

The following standard cross-references are provided for products to be tested in Canada. Although these are parallel Canadian standards, the requirements may differ from those of ASTM standards.

ASTM *Standard* E1529	There is no Canadian equivalent standard on this subject

Corrosion Under Insulation

Corrosion of metal pipe, vessels, and equipment under insulation, though not typically caused by the insulation, is still a significant issue that must be considered during the design of any mechanical insulation system. The propensity for corrosion depends on many factors, including the ambient environment, operating temperature of the metal, proper installation, and maintenance of the insulated system.

Corrosion under insulation (CUI) is most prevalent in outdoor industrial environments such as refineries and chemical plants. Corrosion can be very costly because of forced downtime of processes and can be a health and safety hazard as well. Although insulation itself may not necessarily be the cause of corrosion, it can be a passive component because it is in direct contact with the pipe or equipment surface.

Very little information is published on corrosion in commercial environments. Although corrosion under insulation is less likely to be a major concern for most insulated surfaces located indoors, it may be a factor on indoor systems that are frequently washed down, such as in the food processing industry.

Water from condensation on cold surfaces can be present on both indoor and outdoor insulation systems if there is damage to the vapor retarder. Hot processes can also be subject to condensation during periods of system shutdown.

The following factors may lead to corrosion under insulation.

- **Water** must be present. Water ingress may occur at some point on insulated surfaces. The entry point for water is through breaks in weatherproofing materials such as lagging, mastic, caulk, or adhesives.
- A general lack of **inspection and maintenance** increases the potential for corrosion.
- **Temperature** affects the rate of corrosion. In general, temperatures up to 175°C increase the corrosion rate (NACE *Standard* SP0198).
- **Contaminants** in the plant environment can accelerate corrosion. For instance, chlorides, sulfates, and other corrosion-causing ions could reside on the insulation's exterior jacket, then be washed into the insulation system by rain or washdown. Other sources of corrosive ions include rainwater, ocean mist, and cooling tower spray, each of which can provide a major and virtually inexhaustible supply of ions. Even if the level of ions in the water is low, significant amounts of ions can accumulate at the pipe surface by a continuing cycle of water penetrations and evaporation. Chloride and other ions only contribute to stress corrosion cracking of stainless steel when water (liquid or vapor) and these ions are present at the surface of a pipe at temperatures above ambient, usually when the surface is above about 60°C and below about 150°C; water and corrosive ions on the pipe surface may contribute to normal oxidative (rusting) corrosion of carbon steel at temperatures between –4 and 175°C [see Kalis (1999) and NACE *Standard* SP0198]. Exposure of the insulation system to water from some outside source is inevitable, so the key to eliminating stress corrosion cracking lies in preventing moisture and ions, even in small amounts, from reaching the metal surface.
- **Insulation** can contain leachable corrosive agents. Information on the potential corrosion of carbon steel by insulation materials is available from tests conducted using ASTM *Standard* C1617. The information may be available from the insulation ASTM material standard or from the insulation manufacturer.
- **Austenitic stainless steels** are particularly susceptible to attack from chlorides. Austenitic stainless steels are generally classified as "18-8s": austenitic alloys containing approximately 18% chromium, 8% nickel, and the balance iron. Besides the basic alloy UNS S30400, these stainless alloys include molybdenum (UNS S31600 and S31700), carbon-stabilized (UNS S321000 and S347000), and low-carbon grades (UNS S30403 and S31603) (NACE *Standard* SP0198).

For outdoor applications, to prevent ingress of moisture and corrosive ions from precipitation, a properly designed, installed, and maintained weather-protective jacket is recommended. For more specific guidelines, consult the insulation material manufacturer. If process temperatures are lower than ambient (even for short periods of time such as during shutdowns), a vapor retarder is also required.

Even with a protective jacket and vapor retarder, it is likely that some moisture and ions will eventually enter the system because of abuse, wear, age, or improper installation. No installation is ideal in any real-world setting. Because most people only consider the chlorides arising from the insulation material, the crucial issue of water and ions infiltrating the insulation system from the environment and yielding metal corrosion remains largely unaddressed. Thus, painting the pipe is the second and most important line of defense, and is necessary if pipe temperature is in the 60 to 150°C range for significant periods of time. To minimize the potential for corrosion, metal pipe should be primed with, for example, an epoxy coating. This alternative offers superior protection against corrosion, because priming protects against ions arising from the insulation and, more importantly, from ions that enter the system from the environment.

To minimize corrosion,

- Design, install, and maintain insulation systems to minimize ponding water or penetration of water into the system. Flat sections should be designed with a pitch to shed water. Top sections should overlap the sides to provide a watershed effect on ducts, preventing water penetration in the seam. Jacketing joints should be oriented so as to shed water. Design should always minimize penetrations; necessary protrusions (e.g., supports, valves, flanges) should be designed to shed rather than capture water. Water from external sources can enter at any discontinuity in the insulation system.
- Insulation should be appropriate for its intended application and service temperature. NACE *Standard* RP0198 states, "CUI of carbon steel is possible under all types of insulation. The insulation type may only be a contributing factor. The insulation characteristics with the most influence on CUI are (1) water-leachable salt content in insulation that may contribute to corrosion, such as chloride, sulfate, and acidic materials in fire retardants; (2) water retention, permeability, and wettability of the insulation; and (3) foams containing residual compounds that react with water to form hydrochloric or other acids. Because CUI is a product of wet metal exposure duration, the insulation system that holds the least amount of water and dries most quickly should result in the least amount of corrosion damage to equipment."
- Ancillary materials used for weatherproofing (e.g., sealants, caulks, weather stripping, adhesives, mastics) should be appropriate for the application, and be applied following the manufacturer's recommendations.
- Maintenance should monitor for and immediately repair compromises in the protective jacketing system. Because water may infiltrate the insulation system, inspection ports should be used to facilitate inspection without requiring insulation removal. This is particularly important on subambient systems.
- Because some water will eventually enter the system, a protective pipe coating is necessary for good design. The type of coating depends on temperature (see NACE *Standard* RP0198 for coating guidelines). In Europe, essentially all piping is coated for corrosion protection. This is not necessarily the case in the United States, but should be considered as part of good design practice.
- When using austenitic stainless steel, all insulation products and accessories should meet the requirements of ASTM *Standard* C795 if the system will operate at or spend time between 60 and

Licensed for single user. © 2021 ASHRAE, Inc.

150°C. Likewise, any ancillary weatherproofing materials should have low chloride content.

2. MATERIALS AND SYSTEMS

Categories of Insulation Materials

Turner and Malloy (1981) categorized insulation materials into four types:

- **Fibrous** insulations are composed of small-diameter fibers that finely divide the air space. The fibers may be organic or inorganic, and are normally (but not always) held together by a binder.
- **Granular** insulations are composed of small nodules that contain voids or hollow spaces. These materials are sometimes considered open-cell materials, because gases can transfer between the individual spaces.
- **Cellular** insulations are composed of small, individual cells, either interconnecting or sealed from each other, to form a cellular structure. Glass, plastics, and rubber may comprise the base material, and various foaming agents are used.

  Cellular insulations are often further classified as either open-cell (i.e., cells are interconnecting) or closed-cell (i.e., cells sealed from each other). Generally, materials with greater than 90% closed-cell content are considered to be closed-cell materials.
- **Reflective** insulations and treatments are added to surfaces to lower long-wave emittance, thereby reducing radiant heat transfer from the surface. Low-emittance jackets and facings are often used in combination with other insulation materials.

Another material sometimes called **thermal insulating paint** or **coating** is available for use on pipes ducts and tanks. These products' performance must be clearly understood before using them as thermal insulation. These paints and coatings have not been extensively tested and additional research is needed to verify their performance. Further discussion of these products can be found in Hart (2006).

Physical Properties of Insulation Materials

Selecting an insulation material for a particular application requires understanding the various physical properties associated with available materials.

Operating temperature is often the primary consideration. Maximum temperature capability is normally assessed using ASTM *Standard* C411 by exposing samples to hot surfaces for an extended time, and assessing the materials for any changes in properties. Evidence of warping, cracking, delamination, flaming, melting, or dripping are indications that the maximum use temperature of the material has been exceeded. There is currently no industry-accepted test method for determining the minimum operating temperature of an insulation material, but minimum temperatures are normally determined by evaluating the material's integrity and physical properties after exposure to low temperatures.

Thermal conductivity of insulation materials is a function of temperature. Many specifications call for insulation conductivity values evaluated at a mean temperature of 24°C. Most manufacturers provide conductivity data over a range of temperatures to allow evaluations closer to actual operating conditions. Conductivity of flat product is generally measured per ASTM *Standards* C177 or C518, whereas pipe insulation conductivity is generally determined using ASTM *Standard* C335. Additional information on this property is presented in the following section.

Compressive resistance is important where the insulation must support a load without crushing (e.g., insulation inserts in pipe hangers and supports). When insulation is used in an expansion or contraction joint to take up a dimensional change, lower values of compressive resistance are desirable. ASTM *Standard* C165 is used to measure compressive resistance for fibrous materials, and ASTM *Standard* D1621 is used for foam plastic materials.

Water vapor permeability is the water vapor flux through a material induced by a unit vapor pressure gradient across the material. For insulating materials, it is commonly expressed in units of ng/(s·m·Pa). A related and often-confused term is **water vapor permeance** [in ng/(s·m^2·Pa)], which measures water vapor flux through a material of specific thickness and is generally used to define vapor retarder performance. In below-ambient applications, it is important to minimize the rate of water vapor flow to the cold surface. This is normally accomplished by using vapor retarders or insulation materials (e.g., cellular glass insulation) with a permeance less than or equal to 1.15 ng/(s·m^2·Pa), or both. However, some flexible closed-cell insulation materials have been used successfully without a separate vapor retarder material. ASTM *Standard* E96 is used to measure water vapor transmission properties of insulation materials.

Water absorption is generally measured by immersing a sample of material under a specified pressure of water for a specified time period. It is a useful measure of the amount of liquid water absorbed from water leaks in weather barriers or during construction.

Typical physical properties of interest are given in Table 8. Values in this table are taken from the relevant ASTM material specification with permission from ASTM International. Within each material category, a variety in types and grades of materials exist. A representative type and grade are listed in Table 8 for each material category; refer to ASTM standards or to manufacturers for specific data.

Thermal Conductivity of Below-Ambient Pipe Insulation Systems. Mechanical pipe insulation systems are installed around cold cylindrical surfaces, such as chilled pipes, and work below ambient temperature in several industrial and commercial building applications. Thermal performance of a pipe insulation system is affected by ambient temperature and humidity and might vary gradually with time. For below-ambient temperature applications of pipe insulation, most published data are extrapolated from flat slab configurations of insulation material, and may not be accurate for cylindrical pipe insulation systems because of radial configuration and longitudinal split joints. Thus, ASHRAE research project RP-1356 (Cremaschi et al. 2012) developed an experimental apparatus to measure the thermal conductivity of mechanical pipe insulation systems below ambient temperature. Thermal conductivities of five pipe insulation systems under low-humidity, noncondensing conditions are provided in Table 9 at mean insulation temperatures of 13 and 24°C; the insulation was installed on a 75 mm nominal pipe size diameter aluminum pipe, and the test specimens were 1 m long. Radial heat flux was inward and ranged from 7.6 to 33.3 W/m. Nominal wall thickness of the pipe insulation systems varied from 250 to 500 mm. Vapor barriers on the outer surface of the pipe insulation were not installed. The dry test were performed with the aluminum pipe surface temperature at 4.7°C ± 0.3 K, ambient temperature from 22.8 to 43.3°C, and air dew-point temperature below 4.4°C. For these test conditions, water vapor does not condense on the aluminum pipe surface.

The relation between the pipe insulation's thermal conductivity and its mean temperature is linear, and the thermal conductivity of pipe insulation system had a weak dependence on the nominal wall thickness. Note that, for some cases, joint sealant is recommended for the installation of the pipe insulation. Values in Table 9 represent a combined thermal conductivity of the pipe insulation with a certain type of joint sealant applied on the longitudinal joints, where two C-shells come in contact with each other. The combined thermal conductivity of the pipe insulation might be higher than the thermal conductivity of pipe insulation C-shells that are mechanically joint together without sealant on the longitudinal joints. For example, if a butyl rubber sealant with a layer thickness ranging

from 1.59 to 2.54 mm is used, it is possible that the combined thermal conductivity increases up to 15% with respect to the value of the same pipe insulation system without joint sealant.

ASHRAE research project RP-1356 also measured the thermal conductivity of mechanical pipe insulation systems below ambient temperature in high humidity without vapor retarders, resulting in rapid moisture ingress. Two types of pipe insulation, installed on a 75 mm nominal pipe size diameter aluminum pipe that was 1 m long, were exposed for less than a month to a warm, humid environment, resulting in water vapor condensation in the insulation samples and increased thermal conductivities. The nominal wall thickness of the pipe insulation systems was 50 mm.

Vapor barriers were not installed on the outer surface of the pipe insulation, and the thermal conductivities increased as result of condensed water being retained into the insulation systems. For one type of pipe insulation, the thermal conductivity increased by 3.15 times when the moisture content was about 11% volume. For the other insulation, the thermal conductivity was 1.55 times of the original dry value when the moisture content reached 5% by volume. Each test was run for less than 1 month at high ambient humidity (>80% rh at 35°C. The test conditions were intentionally different from each other, and the thermal performance of the two pipe insulation systems tested in warm, high-humidity conditions should not be compared.

Caution is needed in using this data. Only two types of pipe insulation were tested, and neither had a vapor retarder. The manufacturers of these materials do not recommend these pipe insulation materials be installed in this manner for below-ambient applications. Nevertheless, these data are significant because they demonstrate both the necessity of installing an effective water vapor retarder and the negative impact of water retention in the insulation on its thermal conductivity. These results are only an example of this phenomenon, and any insulation that absorbs and retains water could be similarly affected.

Weather Protection

Weather barriers, often referred to as jacketing, are extremely important. Premature failure can lead to insulation failure, with safety and economic consequences.

Safety consequences

- If insulation is installed for burn protection from a hot pipe or equipment, water entering the insulation system can vaporize into steam and cause a surface temperature well above the expected 60°C, the common design temperature for personnel protection.
- Pipe or equipment can corrode, rupture, and release a hazardous material.

Economic consequences

- Wet insulation has higher thermal conductivity and lower insulation values.
- On a hot system, 1 kg of water entering the system requires 1 kJ to revaporize. If this vapor cannot vent easily, it can condense, causing interior jacket corrosion; the weather barrier will begin consuming itself from the inside out. Consequently, the system cannot deliver the desired energy efficiency and will quickly require an expensive repair.
- On a very cold system, improper vapor retarder selection allows moisture to migrate to the cold surface because of the continuous drive of vapor pressure. A hole in the system allows direct water influx. Either of these entry mechanisms results in ice formation,

Licensed for single user. © 2021 ASHRAE, Inc.

which separates the insulation and weather protection barrier from the pipe or vessel surface and compromises thermal performance.

Many more scenarios must be considered, especially when the broad range of features required of a weather barrier are considered. Turner and Malloy (1981) define a weather barrier as "a material or materials, which, when installed on the outer surface of thermal insulation, protects the insulation from . . . rain, snow, sleet, wind, solar radiation, atmospheric contamination and mechanical damage." With this definition in mind, several service requirements must be considered.

- **Internal mechanical forces**: Expansion and contraction of the pipe or vessel must be considered because the resulting forces are transferred to the external surface of the weather barrier. Ability to slide, elongate, or contract must be provided.
- **External mechanical forces**: Mechanical abuse (i.e., tools being dropped, abrasion from wind-driven sand, personnel walking on the system) inflicted on a pipe or vessel needs to be considered in design. This may affect insulation type, as well as the weather barrier jacketing type.
- **Dimensional stability**: Some cellular materials can show irreversible dimensional change after installation. Manufacturers of these materials provide installation guidelines to minimize the effects of dimensional change. If guidelines are not followed, failure of joint seals can occur, which can lead to system failure.
- **Chemical resistance**: Some industrial environments may have airborne or spilled corrosive agents that accumulate on the weather barrier and chemically attack the pipe or vessel jacketing. Elements that create corrosive issues must be well understood and accounted for. Insulation design of coastal facilities should account for chloride attack.
- **Galvanic corrosion**: Contacts between two different types of metal must be considered for galvanic corrosion potential. Similarly, water can act as an electrolyte, and galvanic corrosion can occur because of the different potential of the pipe or vessel and the metal jacketing.
- **Crevice/pitting corrosion**: Water trapped against the interior surface of a metal weather barrier/jacket can lead to pitting/crevice-type corrosion on the interior surface of the jacket (Young 2011).
- **Insulation corrosivity**: Some insulation materials can cause metal jacket corrosion or chemically attack some polymer films. Both of these situations shorten service life.
- **Thermal degradation**: Hot systems are typically designed so that the surface temperature of the insulation and jacketing material do not exceed 60°C. The long-term effect of 60°C on the jacketing material must be considered. Additionally, there may be solar radiation load and perhaps parallel heat loss from an adjacent pipe. Turner and Malloy (1981) suggest that 120°C should be considered as the long-term operating temperature of the jacketing material selected. This is a critical design consideration, particularly for a nonmetal jacket.
- **Installation and application logistics**: Often, the insulation contractor installs more insulation in a day than can be protected with jacket. If it rains, the exposed insulation gets saturated and, the next day, the jacket is installed over the wet insulation. This creates an obvious potential corrosion and performance issue before the installation is operational, and must be corrected immediately. It should also be understood that the size, shape, and adjacent space available for work may dictate the type of weather barrier used, even if it is a less desirable option. If this is the case, the maintenance schedule must recognize and accommodate for this.
- **Maintenance**: The importance of a maintenance and inspection plan cannot be overemphasized to achieve the service life expected of the design.

Materials Used as Weather Barriers for Insulation. Metal rolls or sheets of various thicknesses are available with embossing, corrugation, moisture barriers, and different banding and closure methods. Elbows and tees are also available for piping. Typical metal jacketing materials are

- Bare aluminum
- Polymer-film-coated aluminum
- Painted aluminum
- Stainless steel
- Painted steel
- Galvanized steel
- Aluminum-zinc coated steel

All metal weather barrier/jacketing should have a 0.76 mm thick multiple-layer moisture barrier factory heat laminated to the interior surface to help prevent galvanic and pitting/crevice corrosion on the interior surface of the jacketing (Young 2011).

Polymeric (plastic) rolls or sheets are available at various thicknesses. These materials are glued or solvent-welded, depending on the polymer. Elbows and tees are also available for piping for some type of polymers. Typical polymeric (plastic) jacketing materials include

- Polyvinyl chloride (PVC)
- Polyvinyliedene chloride (PVDC)
- Polyisobutylene
- Multiple-layer composite materials (e.g., polymeric/foil/mesh laminates)
- Fabrics (silicone-impregnated fiberglass)

Numerous mastics are available. Mastics are often used with fiber-glass cloth or canvas to encapsulate pipes, tanks, or other vessels; they are also used at insulation terminations and at or around protrusions such as valves or supports. It is important to choose the correct mastic for the application, considering surface temperature, insulation type, fire hazard classification, water resistance, and vapor permeability requirements. Mastics are brushed, troweled, or sprayed on the surface at a thickness recommended by the manufacturer.

Importance of Workmanship and Knowledge. Workmanship and knowledge are key to successful insulation weather barrier design. The importance of working with the installing contractor and material manufacturers regarding fitness for use of each material is paramount. The Midwest Insulation Contractors Association (MICA) publishes an excellent resource regarding materials used as weather barriers: the *National Commercial and Industrial Insulation Manual* (2011), in print and as a PDF file, is available from www.micainsulation.org/standards-manual.html.

Vapor Retarders

Water vapor control is extremely important for piping and equipment operating below ambient temperatures. These systems are typically insulated to prevent surface condensation and control heat gain. Piping and equipment typically create an absolute barrier to passage of water vapor, so any vapor-pressure difference imposed across the insulation system results in the potential for condensation at the cold surface. A high-quality vapor retarder material or system is essential for these systems to perform adequately. Mumaw (2001) showed that the design, installation, and performance of the vapor retarder systems are key to an insulation system's ability to minimize water vapor ingress. This research also suggests that in-place system vapor permeance may be greater than the rated performance based on standard material test methods.

Moisture-related problems include thermal performance loss, health and safety issues, structural degradation, corrosion, and aesthetic issues. Water may enter the insulation system through water vapor diffusion, air leakage carrying water vapor, and leakage of surface water. A vapor retarder is a material or system that

Licensed for single user. © 2021 ASHRAE, Inc.

adequately reduces the transmission of water vapor through the insulation system. The vapor retarder system is seldom intended to resist the entry of surface water or prevent air leakage, but can occasionally be considered the second line of defense for these moisture sources.

The performance of the vapor retarder material or system is characterized by its water vapor permeance. Chapter 25 has a thorough description of the physics associated with water vapor transport. Water vapor permeance can be evaluated per ASTM *Standard* E96, using either procedure A (desiccant method) or procedure B (water method), by imposing a vapor pressure difference across vapor retarder material that has been sealed to a test cup, and gravimetrically measuring the moisture gain or loss. It is recommended that both tests be performed and the results of both be evaluated.

Faulty application can impair vapor retarder performance. The effectiveness of installation and application techniques must be considered when selecting a vapor retarder system. Factors such as vapor retarder structure, number of joints, mastics and adhesives that are used, and inspection procedures affect performance and durability.

The insulation system should be dry before application of a vapor retarder to prevent trapping water vapor in the system. The system must be protected from undue weather exposure that could introduce moisture into the insulation before the system is sealed.

When selecting a vapor retarder, the vapor pressure difference across the insulation system should be considered. Higher vapor pressure differences typically require a lower-permeance vapor retarder to control water vapor intrusion into the system. Service conditions affect the direction and magnitude of the vapor pressure difference. Unidirectional flow exists when water vapor pressure is constantly higher on one side of insulation system.

Typically, in buildings located in humid climates, vapor pressure differences in unconditioned spaces are significantly greater than in conditioned spaces. For example, in a conditioned space at 24°C and 50% rh, the vapor pressure difference across the insulation system, on 5.6°C chilled-water lines, is less than 0.68 kPa. For below-ambient, insulated pipes running in humid unconditioned spaces, the vapor pressure difference across the insulation system can be as great as 2.7 kPa in the continental United States, and even greater in places with tropical climates. Hence, for below-ambient pipes running in humid unconditioned spaces, the vapor retarder may require a lower vapor permeance than for those same pipes running in conditioned spaces.

Reversible flow exists when vapor pressure may be higher on either side, typically caused by diurnal or seasonal changes on one side of the system. Properties of insulating materials used should be considered. All materials reduce water vapor flow, but low-permeance insulations can add to the overall water vapor transport resistance of the insulation system. Some low-permeability materials are considered to be vapor retarders without any additional jacket material.

Vapor Retarder Jackets. There is some inconsistency in the nomenclature used for materials used as vapor retarders for pipe, tank, and equipment insulation. Designations such as *jacket*, *jacketing*, *facing*, and *all-service jacket* (*ASJ*) are all applied to this component, sometimes interchangeably. On the other hand, the vapor retarder component of insulation for air-handling systems, such as duct wrap and duct board, is typically referred to only as *facing*. The term *vapor diffusion retarder* (*VDR*) is also used to generically describe these materials.

In this chapter, *vapor retarder* denotes the vapor-retarding membrane of the system, but the reader should be aware of the various terms that may be encountered. In addition, some insulation materials are considered vapor retarders in themselves without any additional retarding membrane.

Vapor Retarders for Pipe, Tank, and Equipment Insulation. Materials or combinations of materials used for vapor retarders can take many different forms. Necessarily, one component must be a material that offers significant resistance to vapor passage. A commonly used preformed material for pipe, tank, and equipment vapor retarder applications is laminated white paper, reinforcing glass-fiber scrim, and aluminum foil or metallized polyester film. These products are generally referred to as **all-service jackets (ASJs)**, and meet the requirements of ASTM *Test Method* C1136 with a vapor permeance of 1.15 ng/(s·m^2·Pa), per procedure A of ASTM *Standard* E96; C1136 is the accepted industry vapor retarder material standard for mechanical insulation applications. These facings are commonly used as the outer finish in low-abuse indoor areas; elsewhere, they should be covered by a protective jacket. Many types of insulation are supplied with factory-applied ASJ vapor retarders.

Note that ASJs with exposed paper may have service limitations on below-ambient systems in wet environments, particularly in unconditioned spaces in hot, humid climates. In such spaces, during periods of high humidity, expect condensation to occur on the insulation's surface some of the time (e.g., when relative humidity exceeds 90%). Condensation on the surface can degrade the ASJ by wetting the exposed kraft paper surface, leading to mold growth on the paper, degradation of the paper itself, and/or corrosion of the aluminum vapor retarder component.

In addition to traditional ASJ vapor retarders, low-permeance monolayer plastic film and sheet, ASJ without exposed paper, laminates using aluminum foil, and other types of sheet structures are used in low- and very-low-temperature applications. They usually are water resistant; that is, when condensation occurs on their surface, they do not absorb the water. These are not always referred to as ASJ, and may be either factory applied by the insulation manufacturer or procured separately from the insulation and applied in fabrication shops or in the field. Examples of laminates include 3- to 13-ply sheet materials with thicknesses up to about 0.4 mm; these plies include at least one layer of aluminum foil and many have a permeance < 0.3 ng/(s·m^2·Pa). There are also rubber and asphalt membranes, with an aluminum facing, with the same permeance. An example of one of the plastic films is polyvinylidene chloride (PVDC). This is typically used in more demanding applications, and often is covered by protective jacket. Many of these ASJ facings meet the requirements of ASTM *Standard* C1136, Type VII or VIII, or ASTM *Standard* C921, and generally have a permeance < 1.15 ng/(s·m^2·Pa) per ASTM *Standard* E96, procedure A.

The moisture-sensitive nature of paper and the relative frailty of uncoated aluminum foil can be problematic in the potentially high-humidity environment of unconditioned spaces with below-ambient applications. Exposure to water, either from condensation caused by inadequate insulation thickness or from ambient sources, can cause degradation and distortion of the paper, higher likelihood of mold growth, and foil corrosion, leading to vapor retarder failure. The presence of leachable chloride can promote corrosion of the foil or metallized film. The trend in vapor retarders for pipe insulation is toward structures without exposed paper, such as plastic films, coated metallized films, and better-protected foil laminates. Many have water vapor permeance ratings < 0.3 ng/(s·m^2·Pa).

For most common vapor retarder jackets, matching pressure-sensitive tapes are available for making joint and puncture seals. With careful installation, these can be used to effectively seal joints in the vapor retarder system. In addition, vapor retarder mastics are available; these should be designated as such by their manufacturer and have a low vapor permeance rating, no greater than that of the vapor retarder membrane. Applying mastic thickly enough is critical to providing sufficient permeance. Vapor retarder mastics are typically used where fittings, supports, and other obstructions make a proper vapor seal difficult to achieve. Highly conformable tapes are sometimes used for this purpose, as well. Applied mastic systems are a vapor-retarding layer; they are often called **vapor barriers** by manufacturers, but their vapor resistance is a function of their permeability, thickness, and quality of the mastic application. Also,

Licensed for single user. © 2021 ASHRAE, Inc.

some mastics may not be compatible with certain insulation types. For this reason, always consult the insulation manufacturer for recommendations on the correct type of vapor retarder to use in the application. Weather barrier mastics are not vapor retarder mastics and should not be used for below-ambient applications unless they also have a low vapor permeability or are used in conjunction with a separate vapor retarder.

Below-ambient piping and equipment in general, and below-freezing applications in particular, are the most demanding applications for an insulation vapor retarder. Even though extremely low-permeance [<0.3 ng/(s·m^2·Pa)] vapor retarder materials exist, it is extremely difficult to achieve a perfect barrier in a system that is field installed and includes numerous joints and penetrations. It follows that adequate system design, proper insulation and jacketing material selection, and careful workmanship are all equally important.

For pipes operating at below-ambient temperatures, it is recommended that every 4.5 to 6 lineal metres, or at every fitting, a vapor stop (also called vapor dam) be installed. Should a leak occur in the vapor retarder, a vapor stop isolates vapor intrusion to that pipe insulation section and thereby prevents vapor and condensed water intrusion into the adjacent section(s) of pipe insulation or adjacent fitting insulation. A vapor stop is made by applying a vapor retarder mastic liberally to the pipe surface, for 75 mm along its length, adjacent to the end of the pipe insulation section. After installing that pipe insulation section, the mastic is then applied liberally to the end of the pipe insulation. Using a glass fiber or polyester scrim allows visual confirmation that the mastic is thick enough. For illustrations of vapor stops, see MICA's (2011) *National Commercial and Industrial Insulation Standards*.

Air-Handling Systems. Vapor retarders for equipment and duct insulation take various forms. Because of the relatively less severe and demanding conditions in air-handling systems located in conditioned spaces (because of their higher operating temperatures and lower indoor ambient humidity), current vapor retarder materials have been shown to adequately meet these performance requirements. In general, moisture problems are not often encountered if insulation design is adequate for the application, and some low-permeability insulation materials are used without separate vapor retarders. For fiberglass duct wrap and duct board, a lamination of aluminum **foil, scrim, and kraft paper (FSK)** has long been the material of choice, although flexible vinyl and other white or black facings are occasionally used. All of these facings can be procured separately in roll form, and used on any type of insulation. ASTM *Standard* C1136, type II, is a typical specification for factory-applied vapor retarder on duct insulation (except flexible duct). Flexible (flex) ducting typically incorporates a plastic film or film lamination that contains a metallized substrate as a vapor-retarding component. For outdoor ducts, laminate jacketing, manufacturer-rated to have a low vapor permeance [<0.3 ng/(s·m^2·Pa)] and for outdoor use, can be installed over the previously mentioned types of duct insulation using a compatible tape for closures, to provide protection from both weather exposure and vapor intrusion to the duct insulation.

Application-specific pressure-sensitive tapes or mastics are typically used to seal joints. As in any cold system where a vapor retarder is required, design, selection of materials, and workmanship must be properly addressed. The insulation manufacturer's recommendations should be followed.

3. INSTALLATION

Pipe Insulation

Small pipes can be insulated with cylindrical half-sections of rigid insulation or with preformed flexible material. Larger pipes can be insulated with flexible material or with curved, flat segmented, or cylindrical half, third, or quarter sections of rigid insulation. Fittings (valves, tees, crosses, and elbows) use preformed fitting insulation, fabricated fitting insulation, individual pieces cut from sectional straight-pipe insulation, or insulating cements. Fitting insulations should always be equal in thermal performance to the pipe insulation.

Securing Methods. The method of securing varies with the type of insulation, size of pipe, form and weight of insulation, and type of jacketing (i.e., field- or factory-applied). Insulation with factory-applied jacketing can be secured on small piping by securing the overlapping jacket, which usually includes an integral sealing tape. Additional tape around the circumference may be necessary. Large piping may require supplemental wiring or banding. Insulation on large piping requiring separate jacketing is wired or banded in place, and the jacket is cemented, wired, or banded, depending on the type. Flexible closed-cell materials require no jacket for most applications and are applied using specially formulated contact adhesives.

Insulating Pipe Hangers. All piping is held in place by hangers and supports. Selection and treatment of pipe hangers and supports can significantly affect thermal performance of an insulation system. Thus, it is important that the piping engineer and insulation specifier coordinate during project design to ensure that correct hangers are used and sufficient physical space is maintained to allow for the required thickness of insulation.

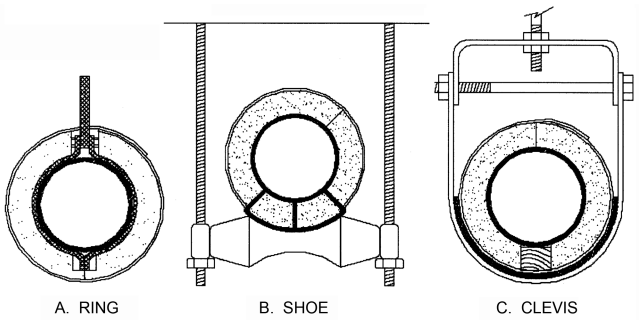

Fig. 6 Insulating Pipe Hangers

A typical **ring** or **line size** hanger is illustrated in Figure 6A. This type of hanger is commonly used on above-ambient lines at moderate temperature. However, it provides a thermal short circuit through the insulation, and the penetration is difficult to seal effectively against water vapor, so it is not recommended for below-ambient applications.

Pipe shoes (Figure 6B) are used for hot piping of large diameter (high mass) and where significant pipe movement is expected. The design allows for pipe movement without damage to the insulation or the finish. The design is not recommended for below-ambient applications because of the thermal short circuit and difficulty in vapor sealing.

A better solution is to use **clevis** hangers (Figure 6C), which are sized to allow clearance for the specified thickness of insulation, and avoid the short circuit associated with ring hangers and pipe shoes. Shields (or saddles) spread the load from the pipe, its contents, and the insulation material over an area sufficient to support the system without significantly compressing the insulation material. Table 10 provides guidance on sheet metal saddle lengths for glass fiber pipe insulation. For pipe sizes above 80 mm, it is recommended that high-compressive-strength inserts (e.g., foam, high-density fiberglass, calcium silicate) be used. Table 11 gives recommended saddle lengths for 32 kg/m^3 polyisocyanurate foam insulation. Preinsulated saddles are available. Note that wood blocks have poor thermal conductivity and are not recommended, especially for cold pipe systems.

When the goal is avoiding compression of low-compressive-strength insulation products, it is recommended to use high-strength insulation inserts, made of a product that offers the desired compressive strength and other necessary performance properties. Other higher-strength materials that are not thermal insulation material and interrupt the insulation envelope, or do not allow complete sealing of an insulation system against water vapor ingress, are not recommended for supporting insulated piping on pipe hangers.

Insulation Finish for Above-Ambient Temperatures. Requirements for pipe insulation finishes for above-ambient applications are usually governed by location. Appearance and durability are the primary design considerations for indoor applications. For outdoor applications, finishes are provided primarily for weather protection. The finishes may be factory-applied jackets or field-applied metal or polymeric jackets.

On indoor steam and hot-water distribution piping, it is common for flange pairs and flanged fittings such as gate valves, butterfly valves, strainers, pressure-relief valves, and other pipe fittings to be left bare (i.e., uninsulated). Whether this is done intentionally or by neglect, the end result is the same: enormous quantities of wasted thermal energy and, in unventilated spaces, very high air temperatures (Hart 2011). It is recommended that all these fittings be insulated with conventional pipe insulation or with removable/reusable insulation blankets, because a bare 175°C steam pipe indoors loses about eight times more heat than does the same pipe with only 25 mm of conventional pipe insulation. If maintenance personnel need ready access to these flanged fittings, removable/reusable insulation blankets are preferable. ASTM *Standard* C1695-10 includes different requirements for indoor and outdoor applications of removable/reusable insulation blankets.

Many blankets used indoors are secured in place using hook-and-loop fastening tape, which allows personnel to remove the insulation, perform maintenance, then reinstall the insulation blankets without tools. Removable/reusable insulation blankets are available either as custom-made components or as kits. If specifying custom-made blankets, time must be allowed in the schedule to have a technical support person measure for the insulation, design and fabricate the blankets, deliver them, and install them. Although ASHRAE *Standard* 90.1-2010 specifies 113 to 125 mm thick insulation on pipes operating above 175°C, it is recommended that permission be sought to use removable/reusable insulation blankets that are 50 mm thick or less for easier removability and reinstallation.

Insulation Finish for Below-Ambient Temperatures. Piping at temperatures below ambient is insulated to limit heat gain and prevent condensation of moisture from the ambient air. Because metallic piping is an absolute barrier to water vapor, it becomes the condensing surface. Therefore, for high-permeability insulation materials [i.e., permeability/thickness combination > 1.15 ng/(s·m^2·Pa)], the outer surface of the insulation should be covered by a low-permeance membrane. However, some flexible closed-cell insulation materials have been used successfully without a separate vapor retarder material.

Vapor retarders for straight pipe insulation are generally designed to meet permeance, operating temperature, fire safety, and appearance requirements. Sheet-type vapor retarders used on below-ambient pipe insulation should have a maximum permeance of 1.15 ng/(s·m^2·Pa), when tested per ASTM *Standard* E96, procedure A (desiccant method) or B (water method). Insulation materials that meet the permeance requirements of an application can be installed without separate vapor retarders, relying on the low permeability and thickness of the insulation material to resist vapor flow, but must be carefully sealed or cemented at all joints to avoid gaps in the insulation. Jacketing used as a vapor retarder may use various materials, alone or in combination, such as paper, aluminum foil, vacuum-metallized or low-permeance plastic films, and reinforcing. The most commonly used products have been ASJ (white), foil-scrim-kraft (FSK), metallized polyester film, or plastic sheeting. An important feature of such jacketing is very low permeance in a relatively thin layer, which provides flexibility for ease of cementing and sealing laps and end-joint strips. This type of jacketing is commonly used indoors without additional treatment. In some cases of operating temperatures below –18°C, multilayer insulation and jacketing may be used. With long lines of piping, insulation should be sealed off every 5 or 6 m with vapor stops to limit water penetration if vapor retarder damage occurs (see Figure 7).

Insulation fittings are usually vapor-sealed by applying suitable materials in the field, and may vary with the type of insulation and operating temperature. The vapor seal can be a lapped spiral wrap of plastic film adhesive tape or a relatively thin coat of vapor-seal mastic. If these do not provide the required permeance, a common practice is to double-wrap a very-low-permeance plastic film adhesive tape or apply two coats of vapor-seal mastic reinforced with open-weave glass or other fabric.

Vapor retarder mastics should be applied in a greater thickness to achieve a lower permeance. Consult the mastic manufacturer for recommendations on the thickness required to achieve a particular permeance.

Insulated cold piping should receive special attention when exposed to ambient or unconditioned air. Because cold piping frequently operates year-round, a unidirectional vapor drive may exist.

Licensed for single user. © 2021 ASHRAE, Inc.

Even with vapor-retarding insulation, jackets, and vapor sealing of joints and fittings, moisture inevitably accumulates in permeable insulations. This not only reduces the thermal resistance of the insulation, it also accelerates condensation on the jacket surface with consequent dripping of water and possible growth of mold and mildew. Depending on local conditions, these problems can arise in less than 3 years, or as many as 30 years. Periodic insulation replacement should be considered, and the piping installation should be accessible for such replacement. Very-low-permeability insulating materials, sometimes in combination with vapor retarders, can be used to extend system life and reduce replacement frequency. This is normally done by using vapor retarders, insulation materials (e.g., cellular glass insulation), or both, with a permeance no more than 1.15 ng/(s·m·Pa). However, some flexible closed-cell insulation materials have been used successfully without a separate vapor retarder material. The lower the insulation system's permeance, the longer its life, given proper installation.

An alternative approach is to accept the inevitable water vapor ingress, and to provide a means of removing condensed water from the system. One means of accomplishing this is the use of a hydrophilic wicking material to remove condensed water from the surface of cold piping for transport (via the combination of capillary forces and gravity) outside the system where it can be evaporated to the ambient air (Brower 2000; Crall 2002; Korsgaard 1993). The wick keeps the hydrophobic insulation dry, allowing the thermal insulation to perform effectively. Dripping is avoided if ambient conditions allow evaporation. The concept is limited to pipe temperatures above freezing.

For dual-temperature service, where pipe operating temperatures cycle, the vapor-seal finish, including mastics, must withstand pipe movement and exposure temperatures without deterioration. When flexible closed-cell insulation is used, it should be applied slightly compressed to prevent it from being strained when the piping expands.

Outdoor pipe insulation may be vapor-sealed in the same manner as indoor piping, by applying added weather protection jacketing without damage to the vapor retarder and sealing it to keep out water. In some instances, heavy-duty weather and vapor-seal finish may be used. It is recommended that weather protection jackets installed over vapor retarders use bands or some other closure method that does not penetrate the weather protection jacketing, because other types have a high likelihood of also penetrating the underlying vapor retarder.

Underground Pipe Insulation. Both heated and cooled underground piping systems are insulated. Protecting underground insulated piping is more difficult than protecting aboveground piping. Groundwater conditions, including chemical or electrolytic contributions by the soil and the existence of water pressure, require special design to protect insulated pipes from corrosion and maintain insulation thermal integrity. For optimal performance, walk-through tunnels, conduits, or integral protective coverings are generally provided to protect the pipe and insulation from water. Examples and general design features of conduits, tunnels, and direct-burial systems can be found in Chapter 12 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*.

Tanks, Vessels, and Equipment

Flat, curved, and irregular surfaces, such as tanks, vessels, boilers, and chimney connectors, are normally insulated with flexible or semirigid sheets or boards or rigid insulation blocks fabricated to fit the specific application. Tank and vessel head segments must be curved or flat cut to fit in single piece or segments per ASTM *Standard* C450. Head segments must be cut to eliminate voids at the head section, and in a minimum number of pieces to minimize joints. Prefabricated flat head sections should be installed in the same number of layers and thickness as the vessel walls, and void areas behind the flat head should be filled with packable insulation. Typically, the curved segments are fabricated to fit the contour of the vessel surface in equal pieces to go around the vessel with a minimum number of joints. Because no general procedure can apply to all materials and conditions, manufacturers' specifications and instructions must be followed for specific applications.

Securing Methods. Insulations are secured in various ways, depending on the form of insulation and contour of the surface to be insulated. Flexible insulations are adhered to tanks, vessels, and equipment using contact adhesive, pressure-sensitive adhesives, or other systems recommended by the manufacturers. The insulation's flexibility lends itself to curved surfaces. Rigid or semirigid insulations on small-diameter, cylindrical vessels can be prefabricated and adhered or mechanically attached, as appropriate. On larger cylindrical vessels, angle iron ledges to support the insulation against slippage can supplement banding. Where diameters exceed 3 to 4 m, slotted angle iron may be run lengthwise on the cylinder, at intervals around the circumference to secure and avoid an excessive length of banding.

Rigid and semirigid insulations can be secured on large flat and cylindrical surfaces by banding or wiring and can be supplemented by fastening with various welded studs at frequent intervals. Springs may be necessary on banding to allow for expansion/contraction of the tank and insulation. On large flat, cylindrical, and spherical surfaces, it is often advantageous to secure the insulation by impaling it on welded studs or pins and fastening it with speed washers. Flexible closed-cell insulations are adhered directly to these surfaces, using a suitable contact adhesive.

Insulation Finish. Insulation finish is often required to protect insulation against mechanical damage and weather, consistent with acceptable appearance. On smaller indoor equipment, insulation is commonly covered with tightly stretched and secured hexagonal wire mesh. Then, a base and hard finish coat of cement is applied, and sometimes painted. For the same equipment outdoors, insulation can be finished with a coat of hard cement, properly secured hexagonal mesh, and a coat of weather-resistant mastic. A variation is to apply only two coats of weather-resistant mastic reinforced with open-mesh glass or other fabric; however, this finish is limited to an operating temperature of about 150°C, because metal expansion can rupture the finish at insulation joints. Larger equipment may be finished indoors and out with suitable sheet metal.

Outdoor finish is generally metal jacketing with a 0.076 mm thick multilayer moisture barrier factory heat laminated to the interior surface, properly flashed around penetrations (e.g., access openings, pipe connections, and structural supports) to maintain weathertightness. Various outdoor finishes are available for different types of insulations.

For below-ambient operating temperatures, insulation is finished, as required, to prevent condensation and protect against mechanical damage and weather, consistent with acceptable appearance. In accordance with the operating temperature, the finish must retard vapor to avoid moisture entry from surrounding air, which can increase the insulation's thermal conductivity or deterioration, or corrode the metal equipment surface.

Whenever a vapor retarder is required, all penetrations such as access openings, pipe connections, and structural supports must be properly treated with an appropriate vapor-retarder film, mastic, or other sealant. Equipment must be insulated from structural steel by isolating supports of high compressive strength and reasonably low thermal conductivity, such as a rigid insulation material. The vapor retarder must carry over this insulation from the equipment to the supporting steel to ensure proper sealing.

If the equipment rests directly on steel supports, the supports must be insulated for some distance from the points of contact.

Licensed for single user. © 2021 ASHRAE, Inc.

Commonly, insulation and vapor retarder are extended four times the thickness of the insulation applied to the equipment.

For dual-temperature service, where vessels are alternately cold and hot, vapor retarder finish materials and design must withstand movement caused by temperature change.

Ducts

Ducts are used to convey air or process gases for several purposes. In general, their uses can be divided into process ducts and HVAC ducts. **Process ducts** can range from industrial hot exhaust to subambient process gases, and can be outdoors or indoors. They can need insulation for various reasons, including thermal energy conservation, personnel protection, process control, condensation control and noise attenuation. Because of the wide range of possible operating temperatures and environmental conditions, selection of duct insulation and jacketing materials for industrial processes requires careful consideration of all operational, environmental, and human safety factors. Issues of energy conservation, personnel protection, condensation control, and process control can be solved by careful analysis of heat flow. Computer programs are available for calculating heat transfer, surface temperatures for personnel protection, condensation control, and economic thickness.

HVAC ducts carry air to conditioned spaces inhabited by people, animals, sensitive equipment, or a combination thereof. Thermal and acoustical duct insulation is one of the keys to a well-designed system that provides both occupant comfort and acceptable indoor air quality (IAQ). These insulation products help maintain a consistent air temperature throughout the system, reduce condensation, absorb system operation noise, and conserve energy.

Typical air temperatures for HVAC applications are 4 to 50°C. Because of the more moderate temperature ranges associated with HVAC applications, there is a wide range of insulation materials available. Where acoustical and thermal considerations are significant, sheet metal ducts are often internally insulated, or the ducts themselves are constructed of materials that form both the air-conveying duct and the insulation. Where acoustical concerns are not significant, sheet metal ducts can be externally insulated with rigid, semirigid, or flexible insulation materials. Again, another alternative is to use ducts that incorporate insulation as part of their construction. The determining factor in duct construction and insulation materials selection is often a combination of performance criteria and budgetary limitations.

The need for duct insulation is influenced by the

- Duct location (e.g., indoors or outdoors; conditioned, semiconditioned, or unconditioned space)
- Effect of heat loss or gain on equipment size and operating cost
- Need to prevent condensation on low-temperature ducts
- Need to control temperature change in long duct lengths
- Need to control noise transmitted within the duct or through the duct wall

All HVAC ducts exposed to outdoor conditions, as well as those passing through unconditioned or semiconditioned spaces, should be insulated. Analyses of temperature change, heat loss or gain, and other factors affecting the economics of thermal insulation are essential for large commercial and industrial projects. ASHRAE *Standard* 90.1 and building codes set minimum standards for thermal efficiency, but economic thickness is often greater than the minimum. Additionally, the standards and codes do not address surface condensation issues. These considerations are often the primary driver of minimum thickness in unconditioned or semiconditioned locations subject to moderate or greater relative humidity.

Duct thermal efficiencies are generally regulated by local or national codes by specifying minimum thermal resistances, or R-values. These R-values are most often determined by testing per ASTM *Standards* C518 or C177, as required by the Federal Trade Commission (FTC) for reporting R-values of duct wrap insulations. Neither method allows for increased thermal resistance caused by convective or radiative surface effects. To comply with current code language, it is recommended that R-value requirements in specifications for duct insulation be based on *Standards* C177 or C518 testing at 24°C mean temperature and at the installed thickness of the insulation. Insulation products for ducts are available in a range of R-values, dependent predominantly on insulation thickness, but also somewhat on insulation density.

Temperature Control Calculations for Air Ducts. Duct heat gains or losses must be known for the calculation of supply air quantities, supply air temperatures, and coil loads (see Chapter 17 of this volume and Chapter 4 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*). Heat loss programs based on ASTM *Standard* C680 may be used to calculate thermal energy transfer through the duct walls. Duct air exit temperatures can then be estimated using the following equations:

$$t_{drop} \text{ or } t_{gain} = \left(\frac{qPL}{VC_p \rho A} \right) \tag{3}$$

then, for warm air ducts,

$$t_{exit} = t_{enter} - t_{drop} \tag{4}$$

and for cold air ducts,

$$t_{exit} = t_{enter} - t_{gain} \tag{5}$$

where

t_{drop} = temperature loss for warm air ducts, K
t_{enter} = entering air temperature, K
t_{gain} = temperature rise for cool air ducts, K
t_{exit} = exit temperature for either warm or cool air ducts, °C
q = heat loss through duct wall, W/m^2
P = duct perimeter, m
L = length of duct run, m
V = air velocity in duct, m/s
C_p = specific heat of air, 1.001 J/(kg·K)
ρ = density of air, 1.20 kg/m^3
A = area of duct, m^2

Example 1. A 20 m length of 0.6 by 0.9 m uninsulated sheet metal duct, freely suspended, conveys heated air through a space maintained at 4°C. The ASTM *Standard* C680 heat loss calculation gives a heat transfer rate of 444 W/m^2. Based on heat loss calculations for the heated zone, 8.1 m^3/s of standard air [c_p = 1006 J/(kg·K)] at a supply air temperature of 50°C is required. The duct is connected directly to the heated zone. Determine the temperature of the air entering the duct.

Solution: The area of the duct is 0.6 × 0.9 = 0.54 m^2.

Air velocity V is calculated as

$$\frac{\text{Volumetric flow}}{\text{Area}} = \frac{8.1}{0.54} = 15 \text{ m/s}$$

Duct perimeter P is

$$(0.6 + 0.9) \times 2 = 3 \text{ m}$$

Temperature drop t_{drop} is

$$\frac{444 \times 3 \times 20}{15 \times 1006 \times 1.20 \times 0.54} = 2.7 \text{ K}$$

Temperature of air entering the duct is thus

$$50 + 2.7 = 52.7°C$$

Example 2. Repeat Example 1, except the duct is insulated externally with 25 mm thick insulation material having a heat transfer rate of 44.7 W/m^2.

Solution: All values except q remain the same as in the previous example. Therefore, t_{drop} is

Licensed for single user. © 2021 ASHRAE, Inc.

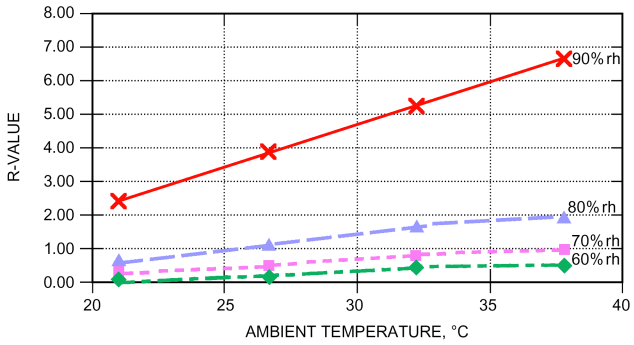

Fig. 7 R-Value Required to Prevent Condensation on Surface with Emittance ε = 0.1

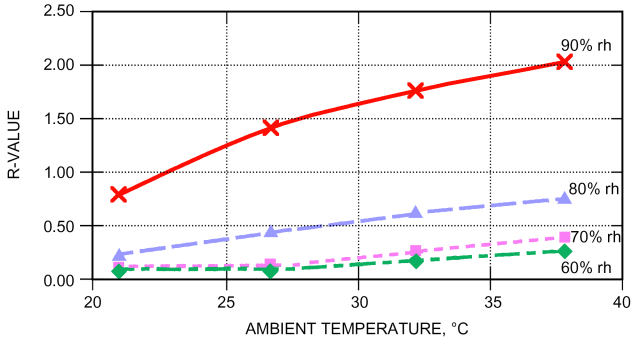

Fig. 8 R-Value Required to Prevent Condensation on Surface with Emittance ε = 0.9

$$\frac{44.7 \times 3 \times 20}{15 \times 1006 \times 1.20 \times 0.54} = 0.27 \text{ K}$$

Temperature of air entering the duct is thus

$$50 + 0.3 = 50.3°C$$

Preventing Surface Condensation on Cool Air Ducts. Insulation also can prevent surface condensation on cool air ducts operating in warm and humid environments. This reduces the opportunity for microbial growth as well as other moisture-related building damage. Condensation forms on cold air-conditioning ducts anywhere the exterior surface temperature reaches the dew point. The moisture may remain in place or drip, causing moisture damage and creating a potential for microbial contamination.

Preventing surface condensation requires that sufficient thermal resistance be installed for the condensation design conditions. Figures 7 and 8 give installed R-value requirements to prevent surface condensation on insulated air ducts. The first chart (for emittance = 0.1) should be used for foil-faced insulation products. The second chart is based on materials with a surface emittance of 0.9. The designer must choose the appropriate environmental conditions for the location. It may be financially imprudent to design for the most extreme condition that could occur during a system's life, but it is also important to be aware that the worst-case condition for condensation control is not the maximum design load of coincident dry bulb and wet bulb. Rather, the worst case for condensation occurs when relative humidity is high, such as when the dry bulb is only very slightly above the wet bulb. This condition often occurs in the early morning in many climates.

For cold-duct applications, it is critical that water vapor not be allowed to enter the insulation system and condense on the cold duct surface. Once water begins to condense, loss of thermal efficiency is inevitable. This leads to further surface condensation on the surface of the insulation. To prevent this, exterior duct insulations must have a low vapor permeance. Permeance values of 5.75 ng/(s·m^2·Pa) or less are generally recommended for cold-duct applications. It is equally important that all exterior duct insulation joints are well sealed. Areas of special concern are often found around duct flanges, hangers, and other fittings.

Insulation Materials for HVAC Ducts. Insulated ducts in buildings can consist of insulated sheet metal, fibrous glass, or insulated flexible ducts, all of which provide combined air barrier, thermal insulation, and some degree of sound absorption. Ducts embedded in or below floor slabs may be of compressed fiber, ceramic tile, or other rigid materials. Depending on the insulation material, there are a number of standards that specify the material requirements.

Duct insulations include semirigid boards and flexible blanket types, composed of organic and inorganic materials in fibrous, cellular, or bonded particle forms. Insulations for exterior surfaces may have attached vapor retarders or facings, or vapor retarders may be applied separately. When applied to the duct interior as a liner, insulation both insulates thermally and absorbs sound. Duct liner insulations have sound-permeable surfaces on the side facing the airstream capable of withstanding duct design air velocities or duct cleaning without deterioration.

Abuse Resistance. One important consideration in the choice of external insulations for air ducts is abuse resistance. Some insulation materials have more abuse resistance than others, but most insulation materials will not withstand high abuse such as foot traffic. In high-traffic locations, a combination of insulation and protective jacketing materials is required. In areas where the insulation is generally inaccessible to human contact, less rigid insulations are acceptable.

One important consideration for internal insulation abuse resistance is that, in large commercial units, it is common for maintenance personnel to enter and move around. In these instances, it is critical that structural elements be provided to keep foot traffic off the insulation.

Duct Airstream Surface Durability. One of the most important considerations in choosing internal duct insulations is resistance to air erosion. Each material has a maximum airflow velocity rating, which should be determined using an erosion test methodology in accordance with either UL *Standard* 181 or ASTM *Standard* C1071. Under these methods, the liner material is subjected to velocities that are two and one-half times the maximum rated air velocity. Air erosion testing should include evaluation of the insulation for evidence of erosion, cracking, or delamination.

Additionally, internal insulation must be resistant to aging effects in the air duct environment. Insulation materials have maximum temperatures for prolonged exposure, and some codes impose temperature requirements. Ensure that the material selected will have no aging effects at either the anticipated maximum duct temperature or the temperature specified by the code bodies for the local jurisdiction.

Another durability concern is ultraviolet (UV) resistance. Ultraviolet-generating equipment is used to mitigate microbial activity. Determine, both from the UV equipment manufacturer as well as the insulation manufacturer, whether the anticipated UV exposure poses a threat to the insulation.

Duct Airflow Characteristics. Internal duct insulations and ducts that have insulation as part of their construction have increased frictional pressure loss characteristics compared to bare sheet metal. Generally, duct dimensions are oversized to compensate for the increased frictional pressure losses and the decrease in internal cross section caused by the insulation thickness. However, frictional losses are only part of the total static pressure loss in a duct; dynamic fitting losses should also be considered in any required resizing. Generally,

Licensed for single user. © 2021 ASHRAE, Inc.

internal linings conform to the shape of the fitting in which they are installed. For this reason, the insulated fitting is assumed to have the same dynamic pressure loss as the uninsulated fitting of the same dimension. See Chapter 21 for further details on frictional pressure loss characteristics of internal linings and how they affect pressure drop and duct-sizing requirements.

Securing Methods. Exterior rigid or flexible duct insulation can be attached with adhesive, with supplemental preattached pins and clips, or with wiring or banding. Individual manufacturers of these materials should be consulted for their installation requirements. Flexible duct wraps do not require attachment except on bottom duct panels more than 600 mm wide. For larger ducts, pins placed at a maximum spacing of 600 mm or less are sufficient. Internal liners are attached with adhesive and pins, in accordance with industry standards.

Leakage Considerations. To achieve the full thermal benefits of insulation, air ducts should be substantially sealed against leakage under operating pressure. The insulation material should not be counted on to provide leakage resistance, unless the insulation is part of the actual duct. Using the case in Example 1, 10% air leakage from an unsealed duct represents an energy loss of 1.66 times the energy lost through heat transfer through the entire 20 m of uninsulated duct. When that same 10% leakage is compared against an insulated duct, the energy lost through leakage is 15.3 times the losses through heat transfer through the insulation over the entire duct length.

Outdoor Applications. Insulated air ducts located outdoors generally require specific protection against the elements, including water, ice, hail, wind, ultraviolet exposure, vermin, birds, other animals, and mechanical abuse. Strategies for protecting externally insulated ducts located outdoors include protective metal jackets and glass fabric with weather barrier mastic. Note that most of these protective weather treatments do not replace the need for a vapor retarder for cold-duct applications.

Special Considerations.

Cooling-only ducts in cold climates. These applications generally occur in northern climates with ducts that run through unconditioned spaces such as attics. Warm air from the conditioned space enters through registers and into the unused ducts. This relatively moist air then condenses in the cold portions of the duct. Condensation encourages odor problems, mold growth, and degradation of the insulation. In the worst cases, water build-up becomes so excessive that water-soaked or frozen ducts can collapse and break through ceilings. The solution is to completely seal all entry points into the ducts, generally by sealing behind all registers, using a very good vapor retarder such as 0.2 mm polyethylene sheet.

Covering ducts with insulation in attics in hot and humid climates. In an effort to conserve energy, attic insulation levels have been increasing. Often, these attics are insulated with pneumatically applied loose fill insulation. If this insulation comes into contact with duct insulation, it could lower surface temperatures on the facing of the duct insulation below dew point during humid conditions. For this reason, it is important that the ducts be supported so that they are above the attic insulation. Many building codes in humid areas (e.g., Florida) require this, and it should be considered good practice in all humid climates.

4. DESIGN DATA

Estimating Heat Loss and Gain

Fundamentals of heat transfer are covered in Chapter 4, and the concepts are extended to insulation systems in Chapter 25. Steady-state, one-dimensional heat flow through insulation systems is governed by Fourier's law:

$$Q = -kA\,dT/dx \tag{6}$$

where

Q = rate of heat flow, W
A = cross-sectional area normal to heat flow, m^2
k = thermal conductivity of insulation material, W/(m·K)
dT/dx = temperature gradient, °C/m

For flat geometry of finite thickness, the equation reduces to

$$Q = kA(T_1 - T_2)/L \tag{7}$$

where L is insulation thickness, in m.

For radial geometry, the equation becomes

$$Q = kA_2(T_1 - T_2)/[r_2 \ln(r_2/r_1)] \tag{8}$$

where

r_2 = outer radius, m
r_1 = inner radius, m
A_2 = area of outer surface, m^2

The term $r_2 \ln(r_2/r_1)$ is sometimes called the **equivalent thickness** of the insulation layer. Equivalent thickness is the thickness of insulation that, if installed on a flat surface, would equal the heat flux at the outer surface of the cylindrical geometry.

Heat transfer from surfaces is a combination of convection and radiation. Usually, these modes are assumed to be additive, and therefore a combined surface coefficient can be used to estimate the heat flow to and from a surface:

$$h_s = h_c + h_r \tag{9}$$

where

h_s = combined surface coefficient, W/(m^2·K)
h_c = convection coefficient, W/(m^2·K)
h_r = radiation coefficient, W/(m^2·K)

Assuming the radiant environment is equal to the ambient air temperature, the heat loss/gain at a surface can be calculated as

$$Q = h_s A(T_{surf} - T_{amb}) \tag{10}$$

The radiation coefficient is usually estimated as

$$h_r = \varepsilon\sigma(T_{surf}^4 - T_{amb}^4)/(T_{surf} - T_{amb}) \tag{11}$$

where

ε = surface emittance
σ = Stephen-Boltzmann constant, 5.67×10^{-8} W/(m^2·K^4)

Table 12 gives the approximate emittance of commonly used materials.

Controlling Surface Temperatures

A common calculation associated with mechanical insulation systems involves determining the thickness of insulation required to control the surface temperature to a certain value given the operating temperature of the process and the ambient temperature. For example, it may be desired to calculate the thickness of tank insulation required to keep the outer surface temperature at or below 60°C when the fluid in the tank is 232°C and the ambient temperature is 27°C.

At steady state, the heat flow through the insulation to the outer surface equals heat flow from the surface to the ambient air:

$$Q_{ins} = Q_{surf} \tag{12}$$

or

$$(k/X)A(T_{hot} - T_{surf}) = hA(T_{surf} - T_{amb}) \tag{13}$$

Rearranging this equation yields

$$X = (k/h)[(T_{hot} - T_{surf})/(T_{surf} - T_{amb})] \tag{14}$$

Licensed for single user. © 2021 ASHRAE, Inc.

Because the ratio of temperature differences is known, the required thickness can be calculated by multiplying the temperature difference and the ratio of the insulation material conductivity to the surface coefficient.

For this example, assume the surface coefficient can be estimated as 5.7 W/(m^2·K), and the conductivity of the insulation to be used is 0.036 W/(m·K). The required thickness can then be estimated as

$$X = \left(\frac{0.036}{5.7}\right)\left[\frac{(230-60)}{(60-27)}\right] = 0.032 \text{ m or } 32 \text{ mm} \quad (15)$$

This estimated thickness would be rounded up to the next available size, probably 38 mm.

For radial heat flow, the thickness calculated represents the equivalent thickness; the actual thickness ($r_2 - r_1$) is less, per Equation (8).

This simple procedure can be used as a first-order estimate. In reality, the surface coefficient is not constant, but varies as a function of surface temperature, air velocity, orientation, and surface emittance.

When performing these calculations, it is important to use the actual dimensions for the pipe and tubing insulation. Many (but not all) pipe and tubing insulation products conform to dimensional standards originally published by the U.S. Navy in *Military Standard* MIL-I-2781 and since adopted by other organizations, including ASTM. Standard pipe and insulation dimensions are given for reference in Table 13, and standard tubing and insulation dimensions in Table 14. Corresponding dimensional data for flexible closed-cell insulations are given in Tables 15 and 16.

For mechanical insulation systems, it is also important to realize that the thermal conductivity k of most insulation products varies significantly with temperature. Manufacturer's literature usually provides curves or tabulations of conductivity versus temperature. When performing heat transfer calculations, it is important to use the effective thermal conductivity, which can be obtained by integration of the conductivity versus temperature curve, or (as an approximation) using the conductivity evaluated at the mean temperature across the insulation layer. ASTM *Standard* C680 provides the algorithms and calculation methodologies for incorporating these equations in computer programs.

These complications are readily handled for a variety of boundary conditions using available computer programs, such as the NAIMA 3E Plus® program [available as a download from the website of the North American Insulation Manufacturers Association (NAIMA), www.naima.org].

Estimates of the heat loss from bare pipe and tubing are given in Tables 17 and 18. These are useful for quickly estimating the cost of lost energy from uninsulated piping.

5. PROJECT SPECIFICATIONS

The importance of a well-prepared specification to meet energy conservation objectives is paramount. Specifications should

- Identify systems and equipment that must be insulated
- Identify precisely the materials selected, including thickness and jacketing, etc.
- Define the procedure for submitting alternative materials and systems
- Specify installation, inspection, and repair requirements
- Describe procedures to ensure the job is done correctly
- Comply with regional and national building codes

Although each of these steps is important, identifying systems that must be insulated is critical. When defining the materials to be used, it is important to specify them exactly, while allowing for submission of generic equivalents or value-engineered materials. Overspecifying materials limits potentially good options, and underspecifying may allow underperforming materials to be used.

Table 12 Emittance Data of Commonly Used Materials

Material	Emittance ε at ~27°C
All-service jacket (ASJ)	0.9
Aluminum paint	0.5
Aluminum	
Anodized	0.8
Commercial sheet	0.1
Embossed	0.2
Oxidized	0.1 to 0.2
Polished	0.04
Aluminum-zinc coated steel	0.06
Canvas	0.7 to 0.9
Colored mastic	0.9
Copper	
Highly polished	0.03
Oxidized	0.8
Elastomeric or polyisobutylene	0.9
Galvanized steel	
Dipped or dull	0.3
New, bright	0.1
Iron or steel	0.8
Painted metal	0.8
Plastic pipe or jacket (PVC, PVDC, or PET)	0.9
Roofing felt and black mastic	0.9
Rubber	0.9
Silicon-impregnated fiberglass fabric	0.9
Stainless steel	
New, cleaned	0.2
Oxidized in service	0.32

A proper balance is needed, and specifying key properties is required. Specifying installation requirements is as important as specifying the correct materials. Specifying procedures for submittals and quality control at the job ensures correctness.

Reference standards from ASHRAE, ASTM, MICA, and others should be incorporated into the specifications; this practice saves time with respect to specification development, and shortens the specification considerably. Specifications that are not reviewed and updated periodically can perpetuate old technologies and obsolete materials, and fall out of code compliance.

Essentially all manufacturers of mechanical insulation products offer guide specifications for their products. These documents are insightful and offer credible information about specific products and the accessories commonly used with them. These documents are widely available on manufacturers' websites.

AIRFLOW around buildings affects worker safety, process and building equipment operation, pollution infiltration at building inlets, and the ability to control indoor environmental parameters such as temperature, humidity, air motion, and contaminants. Wind causes variable surface pressures on buildings that can change intake and exhaust system flow rates, natural ventilation, infiltration and exfiltration, and interior pressures. The mean flow patterns and turbulence of wind passing over a building can also lead to recirculation of exhaust gases into air intakes.

This chapter provides basic information for evaluating wind flow patterns, estimating wind pressures, and identifying problems caused by the effects of wind on pedestrians and buildings, including ventilation intakes, exhausts, and equipment. In most cases, detailed solutions are addressed in other chapters. Related information can be found in Chapters 11, 14, 16, and 37 of this volume; in Chapters 31, 32, 45, 47, and 53 of the 2019 *ASHRAE Handbook—HVAC Applications*; and in Chapters 30, 35, and 40 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*.

1. FLOW PATTERNS

Flow Patterns Around Isolated, Rectangular Block-Type Buildings

Buildings with even moderately complex shapes, such as L- or U-shaped structures, can generate flow patterns too complex to generalize for design. To determine flow conditions for such buildings, wind tunnel or water channel tests of physical scale models, full-scale tests of existing buildings, or appropriate computational modeling efforts are required (see the section on Physical and Computational Modeling). Thus, only isolated, rectangular block-type buildings are discussed here.

Figure 1 shows the wind flow pattern around a single, wide, high-rise building slab, with the main flow features indicated by numbers. The following description of the flow pattern is adapted from Blocken et al. (2011). As wind impinges on the building, part of the flow is deviated over the building (point 1) and part flows around it (2, 9). A stagnation point is present at the windward façade at about 70% of the building height. From this point, part of the flow is deviated upward (**upwash**) (3), part is deviated sideways (4), and a large part is directed downwards (**downwash**) (5). This downflow develops into a ground-level vortex (6) called standing vortex, frontal vortex, or horseshoe vortex. The main flow direction of this vortex near ground level is opposite to the direction of the approach flow. Both flows collide at the stagnation point at ground level in front of the building (7). The standing vortex subsequently wraps around the building corners, yielding the concentrated **corner streams**, characterized by very high wind speed amplification (8). These corner streams are further amplified by the general ground-level flow around the building (9). At the building's leeward side, the underpressure zone results in recirculation flow (10, 13). A stagnation zone is also present downstream of the building at ground level,

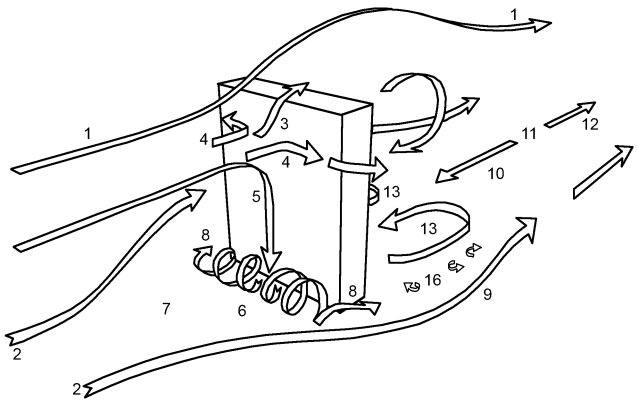

Fig. 1 Wind Flow Pattern Around High-Rise Building Slab
[Adapted from Blocken et al. (2016) and Beranek and Van Koten (1979)]

where the flow directions are opposite and wind speeds are low (11). Further downstream, the wind speed remains low for a considerable distance behind the building (i.e., the far wake) (12). Backflow is also responsible for creating slow-rotating vortices behind the building (13). Between these vortices and the corner streams (9) is a zone with a high velocity gradient (**shear layer**) that comprises small, fast-rotating vortices (16).

Figure 2 provides a more detailed illustration of the wind flow pattern around an isolated building. It more clearly shows the vortical nature of the corner streams, and it indicates the areas of flow separation and reattachment and the flow in the near wake. It is important to note that Figures 1 and 2 only show the mean wind flow pattern, and that the actual flow pattern exhibits pronounced transient features, such as the build-up and collapse of the separation/recirculation bubbles and periodic vortex shedding in the wake (Murakami 1993; Tominaga et al. 2008a).

For a building with height H that is three or more times the width W of the upwind face, an intermediate stagnation zone can exist between the upwash and downwash regions, where surface streamlines pass horizontally around the building (Figure 3A). (In Figure 3, the upwind building surface is "folded out" to illustrate upwash, downwash, and stagnation zones.) Downwash on the lower surface of the upwind face separates from the building before it reaches ground level and moves upwind to form the standing vortex. Figure 3B shows the near-surface flow patterns for oblique approach flow. Strong vortices develop from the upwind edges of the roof, causing strong downwash onto the roof. High speeds in these vortices (**vorticity**) cause large negative pressures near roof corners that can be a hazard to roof-mounted equipment during high winds. In some extreme cases, the negative pressures can be strong enough to lift heavy objects such as roof pavers, which can result in a projectile hazard.

When the angle between the wind direction and the upwind face of the building is less than about 70°, the upwash/downwash patterns on the upwind face of the building are less pronounced, as is the ground-level vortex shown in Figure 1 and 2. Figure 3B shows that,

The preparation of this chapter is assigned to TC 4.3, Ventilation Requirements and Infiltration.

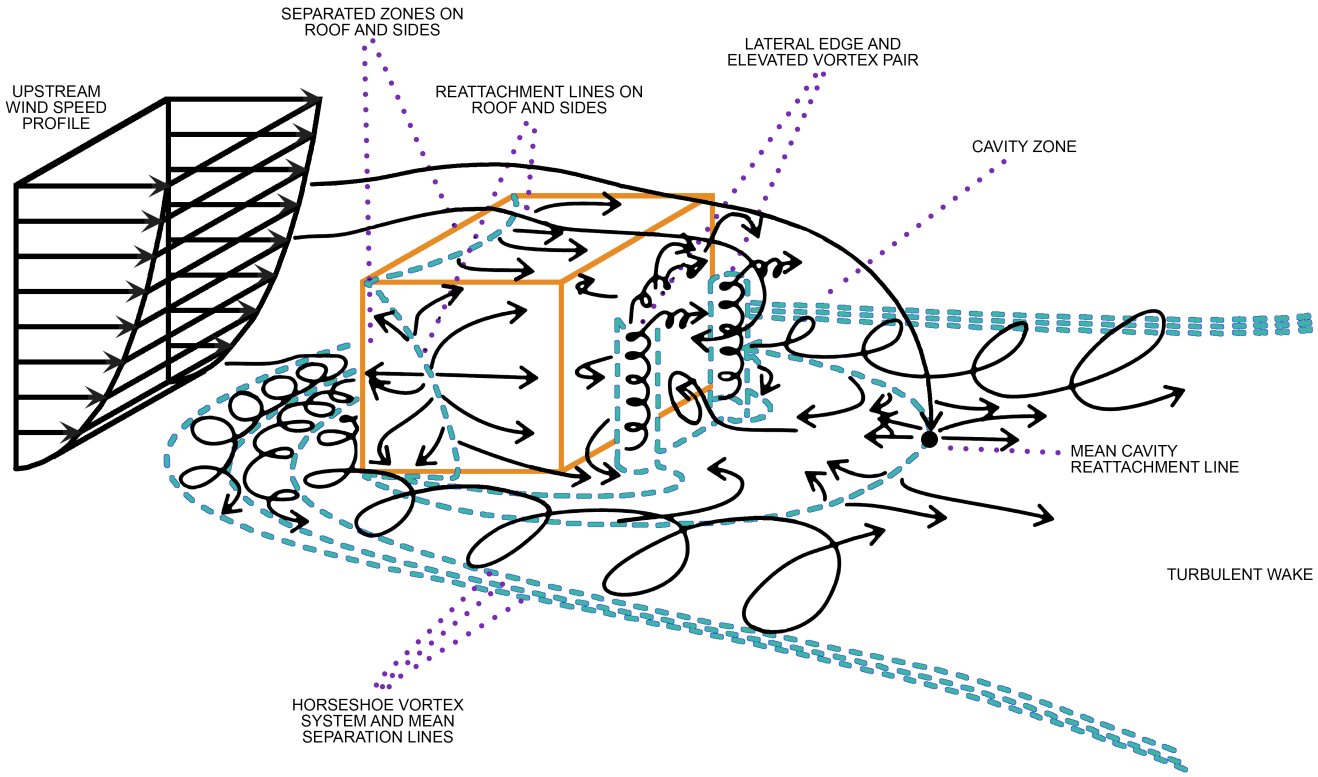

Fig. 2 Wind Flow Pattern Around Isolated Building
(Hunt et al. 1978)

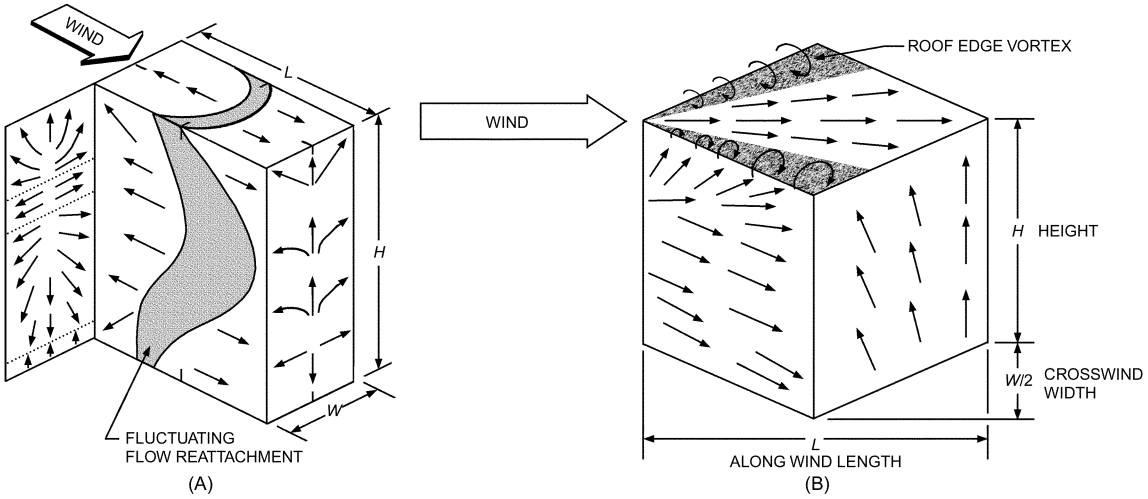

Fig. 3 Surface Flow Patterns for Normal and Oblique Winds
(Wilson 1979)

for an approach flow angle of 45°, streamlines remain close to the horizontal in their passage around the sides of the building, except near roof level, where the flow is drawn upwards into the roof edge vortices (Cochran 1992).

Both the upwind velocity profile shape and its turbulence intensity strongly influence flow patterns and surface pressures (Melbourne 1979).

The downwind wall of a building exhibits a region of low average velocity and high turbulence (i.e., a **flow recirculation** region) extending a distance L_r downwind. If the building has sufficient length L in the windward direction, the flow reattaches to the building and may generate two distinct regions of separated recirculation flow, on the roof of the building and in its wake, as shown in Figure 4. Figure 4 also shows a rooftop recirculation cavity of length L_c at the upwind roof edge and a recirculation zone of length L_r downwind of the rooftop penthouse. Velocities near the downwind wall are typically one-quarter of those at the corresponding upwind wall location. Figures 2 and 3 show that an upward flow exists over most of the downwind walls.

Streamline patterns and the size of the wake(s) are generally independent of wind speed and depend mainly on building shape and upwind conditions. Because of the three-dimensional flow around a

Licensed for single user. © 2021 ASHRAE, Inc.

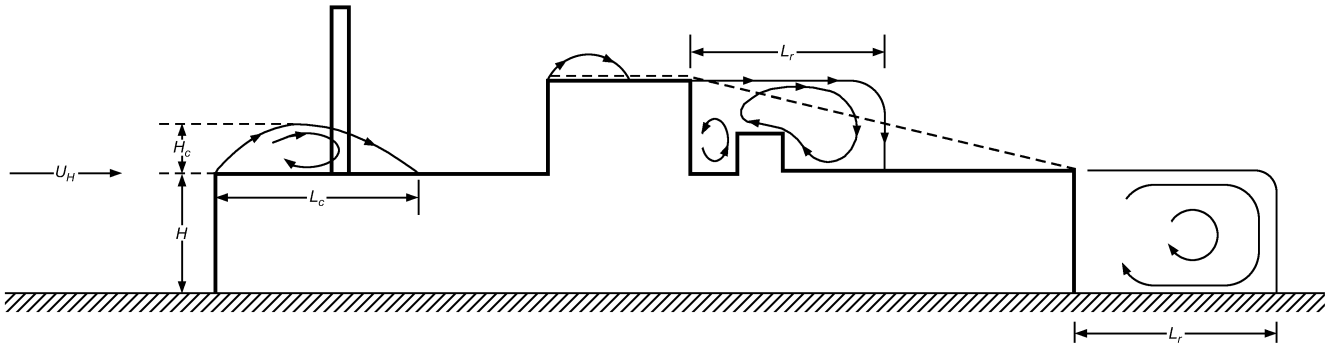

Fig. 4 Flow Recirculation Regions

building, the shape and size of the recirculation airflow are not constant over the surface. Airflow reattaches closer to the upwind building face along the edges of the building than it does near the middle of the roof and sidewalls (Figure 3). Recirculation cavity height H_c (Figure 4) also decreases near roof edges. Calculating characteristic dimensions for recirculation zones H_c, L_c, and L_r is discussed in Chapter 45 of the 2019 *ASHRAE Handbook—HVAC Applications*.

For wind perpendicular to a building wall, the height H and width W of the upwind building face determine the **scaling length** R that characterizes the building's influence on wind flow. According to Wilson (1979),

$$R = B_s^{0.67} B_L^{0.33} \quad (1)$$

where

B_s = smaller of upwind building face dimensions H and W
B_L = larger of upwind building face dimensions H and W

When B_L is larger than $8B_s$, use $B_L = 8B_s$ in Equation (1). For buildings with varying roof levels or with wings separated by at least a distance of B_s, only the height and width of the building face below the portion of the roof in question should be used to calculate R.

Flow accelerates as the streamlines compress over the roof and decelerates as they spread downward over the wake on the downwind side of the building. The height above roof level where a building influences the flow is approximately $1.5R$. In addition, roof pitch also begins to affect flow when it exceeds about 15° (1:4). When roof pitch reaches 20° (1:3), flow remains attached to the upwind pitched roof and produces a recirculation region downwind of the roof ridge that is larger than that for a flat roof.

Flow Patterns Around Building Groups

In building groups, the flow patterns can interact, yielding a higher complexity. To determine flow conditions around building groups, wind tunnel or water channel tests of physical scale models, full-scale tests of existing buildings, or careful computational modeling efforts are required (see the section on Physical and Computational Modeling). English and Fricke (1997), Hosker (1984, 1985), Khanduri et al. (1998), Saunders and Melbourne (1979), and Walker et al. (1996) review the effects of nearby buildings, whereas Blocken et al. (2007a, 2008), Stathopoulos and Storms (1986), Yoshie et al. (2007), and others assess the effects of nearby buildings by wind tunnel testing and computational modeling. To illustrate the complexity of wind flow patterns induced by nearby buildings, Figure 5 provides a top view of two high rise buildings in V shape. Depending on the wind direction, this configuration is labeled as converging or diverging. Although the highest wind speed in the passage between both buildings might be expected to occur for the converging arrangement, wind tunnel tests and numerical simulations indicate that the diverging arrangement actually has higher wind speed. This is shown by the

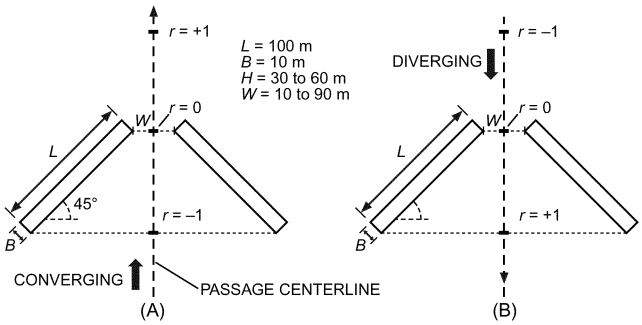

Fig. 5 Buildings in (A) Converging and (B) Diverging Configuration

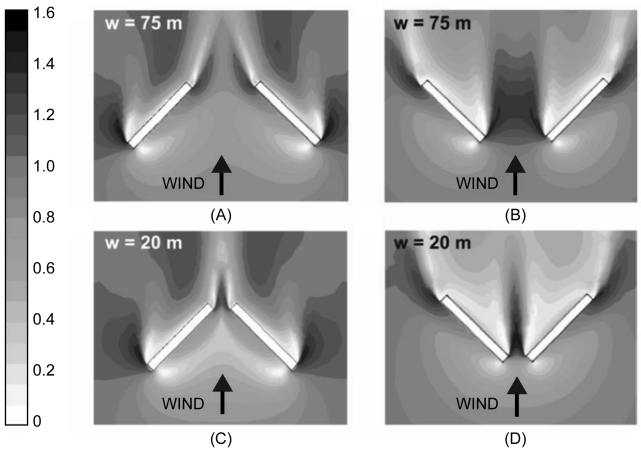

Fig. 6 Amplification Factor K in Horizontal Plane at $y = 2$ m above Ground for Converging and Diverging Arrangement with $H = 30$ m and $w = 75$ m and 20 m
(Blocken et al. 2008)

amplification factors in Figure 6, which are defined as the ratio of the local wind speed to the wind speed that would occur at the same height in absence of the buildings. The higher amplification factor in the diverging arrangement is caused by the lesser flow resistance in this configuration. The Venturi effect does not apply in this case: the Venturi effect refers to confined flows, whereas wind flow in the atmosphere is unconfined. Further information on this study can be found in Blocken et al. (2008).

Figure 7 shows the flow over building arrays with increasing H/W. The description of these flow patterns is adopted from Oke (1988). If the buildings are sufficiently apart ($H/W > 0.05$), their flow fields do

Licensed for single user. © 2021 ASHRAE, Inc.

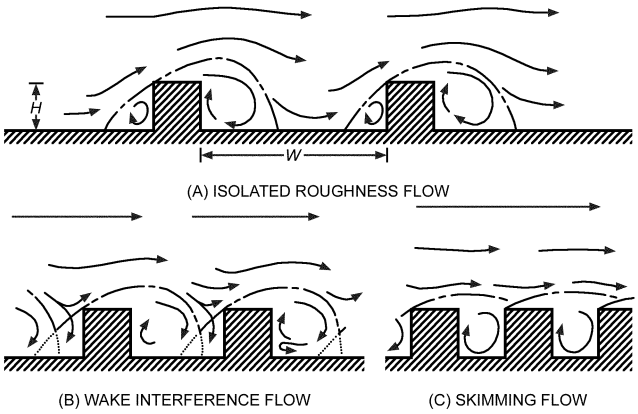

Fig. 7 Flow Regimes Associated with Airflow over Building Arrays of Increasing *H*/*W*
(Oke 1988)

not interact, and the flow is called **isolated roughness flow**. When the buildings are positioned closer together, their flow patterns show some degree of interaction, mainly manifested as a disturbance of the wake structure (**wake interference flow**). When the ratio H/W increases further, a stable circulatory vortex is formed in the canyon and the bulk of the flow does not enter the canyon (**skimming flow**).

2. WIND PRESSURE ON BUILDINGS

In addition to flow patterns described previously, the turbulence or gustiness of approaching wind and the unsteady character of separated flows cause surface pressures to fluctuate. Pressures discussed here are time-averaged values, with a full-scale averaging period of about 600 s. This is approximately the shortest time period considered to be a "steady-state" condition when considering atmospheric winds; the longest is typically 3600 s. Instantaneous pressures may vary significantly above and below these averages, and peak pressures two or three times the mean values are possible. Peak pressures are important with regard to structural loads, and mean values are more appropriate for computing infiltration and ventilation rates. Time-averaged surface pressures are proportional to wind velocity pressure p_v given by Bernoulli's equation:

$$p_v = \frac{\rho_a U_H^2}{2} \tag{2}$$

where

p_v = wind velocity pressure at roof level, Pa
U_H = approach wind speed at upwind wall height H, m/s [see Equation (4)]
ρ_a = ambient (outdoor) air density, kg/m^3

The proportional relationship is shown in the following equation, in which the difference p_s between the pressure on the building surface and the local outdoor atmospheric pressure at the same level in an undisturbed wind approaching the building is

$$p_s = C_p p_v \tag{3}$$

where C_p is the local wind pressure coefficient at a point on the building surface.

Approach Wind Speed

The local wind speed U_H at the top of the wall required for Equation (2) is estimated by applying terrain and height corrections to the hourly wind speed U_{met} from a nearby meteorological station.

U_{met} is generally measured in flat, open terrain (i.e., category 3 in Table 1). The anemometer that records U_{met} is located at height H_{met}, usually 10 m above ground level. The hourly average wind speed U_H in the undisturbed wind approaching a building in its local terrain can be calculated from U_{met} as follows:

$$U_H = U_{met}\left(\frac{\delta_{met}}{H_{met}}\right)^{a_{met}}\left(\frac{H}{\delta}\right)^{a} \tag{4}$$

Table 1 Atmospheric Boundary Layer Parameters

Terrain Category	Description	Exponent a	Layer Thickness δ, m
1	Large city centers, in which at least 50% of buildings are higher than 25 m, over a distance of at least 0.8 km or 10 times the height of the structure upwind, whichever is greater	0.33	460
2	Urban and suburban areas, wooded areas, or other terrain with numerous closely spaced obstructions having the size of single-family dwellings or larger, over a distance of at least 460 m or 10 times the height of the structure upwind, whichever is greater	0.22	370
3	Open terrain with scattered obstructions having heights generally less than 9 m, including flat open country typical of meteorological station surroundings	0.14	270
4	Flat, unobstructed areas exposed to wind flowing over water for at least 1.6 km, over a distance of 460 m or 10 times the height of the structure inland, whichever is greater	0.10	210

The atmospheric boundary layer thickness δ and exponent a for the local building terrain and a_{met} and δ_{met} for the meteorological station are determined from Table 1. Typical values for meteorological stations (category 3 in Table 1) are $a_{met} = 0.14$ and $\delta_{met} = 270$ m. The values and terrain categories in Table 1 are consistent with those adopted in other engineering applications (e.g., ASCE *Standard* 7). Equation (4) gives the wind speed that occurs at a certain height H above the average height of local obstacles, such as buildings and vegetation, weighted by the plan area. At heights at or below this average obstacle height (e.g., at roof height in densely built-up suburbs), speed depends on the geometrical arrangement of the buildings, and Equation (4) is less reliable.

An alternative mathematical description of the atmospheric boundary layer, which uses a logarithmic function, is given by Deaves and Harris (1978). Although their model is more complicated than the power law used in Equation (4), it more closely models the real physics of the atmosphere and has been adopted by several codes around the world (e.g., SA/SNZ 2002).

Example 1. Assuming a 10 m/s anemometer wind speed for a height H_{met} of 10 m at a nearby airport, determine the wind speed U_H at roof level H = 15 m above grade for a building located in a city suburb.

Solution: From Table 1, the atmospheric boundary layer properties for the anemometer are a_{met} = 0.14 and δ_{met} = 270 m. The atmospheric boundary layer properties at the building site are a = 0.22 and δ = 370 m. Using Equation (4), wind speed U_H at 15 m is

$$U_H = 10\left(\frac{270}{10}\right)^{0.14}\left(\frac{15}{370}\right)^{0.22} = 7.8 \text{ m/s}$$

Local Wind Pressure Coefficients

Values of the mean local wind pressure coefficient C_p used in Equation (3) depend on building shape, wind direction, and influence of nearby buildings, vegetation, and terrain features. Accurate determination of C_p can be obtained only from wind tunnel model

Licensed for single user. © 2021 ASHRAE, Inc.

tests of the specific site and building or full-scale tests. Ventilation rate calculations for single, unshielded rectangular buildings can be reasonably estimated using existing wind tunnel data. Many wind load codes (e.g., ASCE *Standard* 7; ASCE 1999; SA/SNZ *Standard* AS/NZS 1170.2) give mean pressure coefficients for common building shapes.

Figure 8 shows pressure coefficients for walls of a tall rectangular cross section high-rise building sited in urban terrain (Davenport and Hui 1982). Figure 9 shows pressure coefficients for walls of a low-rise building (Holmes 1986). Generally, for high-rise buildings, height H is more than three times the crosswind width W. For $H > 3W$, use Figure 8; for $H < 3W$, use Figure 9. At a wind angle $\theta = 0°$ (e.g., wind perpendicular to the face in question), pressure coefficients are positive, and their magnitudes decrease near the sides and the top as flow velocities increase.

As shown in Figure 8, C_p generally increases with height, which reflects increasing velocity pressure in the approach flow as wind speed increases with height. As wind direction moves off normal ($\theta = 0°$), the region of maximum pressure occurs closer to the upwind edge (B in Figure 8) of the building. At a wind angle of $\theta = 45°$, pressures become negative at the downwind edge (A in Figure 8) of the front face. At some angle θ between 60° and 75°, pressures become negative over the whole front face. For $\theta = 90°$, maximum suction (negative) pressure occurs near the upwind edge (B in Figure 8) of the building side and then recovers towards a lower-magnitude negative coefficient as the downwind edge (A in Figure 8) is approached. The degree of this recovery depends on the length of the side in relation to the width W of the structure. For wind angles larger than $\theta = 100°$, the side is completely within the separated flow of the wake and spatial variations in pressure over the face are not as great. In summary, the average pressure on a face is positive for wind angles from $\theta = 0°$ to almost 60° and negative (suction) for $\theta = 60°$ to 180°.

A similar pattern of behavior in wall pressure coefficients for a low-rise building is shown in Figure 9. Here, recovery from strong suction with distance from the upwind edge is more rapid.

Surface-Averaged Wall Pressures

Surface-averaged pressure coefficients may be used to determine ventilation and/or infiltration rates, as discussed in Chapter 16. Figure 10 shows the surface pressure coefficient C_s averaged over a complete wall of a high-rise building (Akins et al. 1979). Similar results for a low-rise building are shown in Figure 11 (based on methodology of Swami and Chandra 1987). This figure also includes values calculated from pressure distributions in Figure 9.

Roof Pressures

Figure 12 shows the average pressure coefficient over the roof of a tall building (Akins et al. 1979).

Surface pressures on the roof of a low-rise building depend strongly on roof slope. Figure 13 shows typical distributions for a wind direction normal to a side of the building. Note that the direction and magnitude of pressure coefficients are indicated by the direction and length of the arrows. For very low slopes (less than about 10°), pressures are negative over the whole roof surface. The magnitude is greatest within the separated flow zone near the leading edge and recovers toward the free-stream pressure downwind of

the edge. For intermediate slopes (about 10 to 20°), two large-magnitude low-pressure regions a re formed, one at the leading roof edge and another one beginning at the roof peak. For steeper slopes (greater than about 20°), pressures are weakly positive on the upwind slope and negative within the separated flow over the downwind slope.

With a wind angle of about 45°, the vortices originating at the leading corner of a roof with a low slope can induce very large,

localized negative pressures (see Figure 3B). A similar vortex forms on the downwind side of a leading ridge end on a steep roof, as discussed in Cochran et al. (1999). Roof corner vortices and how to disrupt their influence are discussed in Cochran and Cermak (1992) and Cochran and English (1997).

Interference and Shielding Effects on Pressures

Nearby structures strongly influence surface pressures on both high- and low-rise buildings, particularly for spacing-to-height ratios less than five, where distributions of pressure shown in Figures 8 to 13 do not apply. Although the effect of shielding for low-rise buildings is still significant at larger spacing, it is largely accounted for by the reduction in p_v with increased terrain roughness. Bailey and Kwok (1985), Khanduri et al. (1998), Saunders and Melbourne (1979), Sherman and Grimsrud (1980), and Walker et al. (1996) discuss interference. English and Fricke (1997) discuss shielding through use of an interference index, and Walker et al. (1996) present a wind shadow model for predicting shelter factors. Chapter 16 gives shielding classes for air infiltration and ventilation applications.

3. SOURCES OF WIND DATA

Wind at Recording Stations

To design buildings taking into account wind effects, wind speed and direction frequency data are necessary. The simplest forms of wind data are tables or charts of climatic normals, which give hourly average wind speeds, prevailing wind directions, and peak gust wind speeds for each month. This information can be found in sources such as *The Weather Almanac* (Bair 1992) and the *Climatic Atlas of the United States* (DOC 1968). Climatic design information, including wind speed at various frequencies of occurrence, is included in Chapter 14. Information on wind speed and direction frequencies is available from the National Climatic Data Center (NCDC) in Asheville, NC. Where more detailed information is required, digital records of hourly winds and other meteorological parameters are available from the NCDC for stations throughout the world. Most countries also have weather services that provide data. For example, in Canada, the Meteorological Service of Canada provides hourly meteorological data and summaries.

When an hourly wind speed U_{met} at a specified probability level (e.g., the wind speed that is exceeded 1% of the time) is desired, but only the average annual wind speed U_{annual} is available for a given meteorological station, U_{met} may be estimated using Table 2. The ratios U_{met}/U_{annual} are based on long-term data from 24 weather stations widely distributed over North America. At these stations, U_{annual} ranges from 3.1 to 6.3 m/s The uncertainty ranges listed in Table 2 are one standard deviation of the wind speed ratios. Example 2 demonstrates the use of Table 2.

Example 2. The wind speed U_{met} that is exceeded 1% of the time (88 hours per year) is needed for a building pressure or exhaust dilution calculation. If $U_{annual} = 4$ m/s, find U_{met}.

Solution: From Table 2, the wind speed U_{met} exceeded 1% of the time is 2.5 ± 0.4 times U_{annual}. For $U_{annual} = 4$ m/s, U_{met} is 10 m/s with an uncertainty range of 8.4 to 11.6 m/s at one standard deviation.

Using a single prevailing wind direction for design can cause serious errors. For any set of wind direction frequencies, one direction always has a somewhat higher frequency of occurrence. Thus, it is often called the **prevailing wind**, even though winds from other directions may be almost as frequent.

When using long-term meteorological records, check the anemometer location history, because the instrument may have been relocated and its height varied. This can affect its directional exposure and the recorded wind speeds. Equation (4) can be used to correct wind data collected at different mounting heights. Poor anemometer exposure caused by obstructions or mounting on top of a building cannot be easily corrected, and records for that period should be deleted.

If an estimate of the probability of an extreme wind speed outside the range of the recorded values at a site is required, the observations may be fitted to an appropriate probability distribution (e.g., a Weibull distribution) and the particular probabilities calculated from the resulting function (Figure 14). This process is usually repeated for each of 16 wind directions (e.g., 22.5° intervals). Note that most recent wind data records are provided in 10° intervals, for which the same method may be used, except that the process is repeated for each of 36 wind directions. If both types of data are to be used, one data set must be transformed to match the other.

Where estimates at extremely low probability (high wind speed) are required, curve fitting at the tail of the probability distribution is very important and may require special statistical techniques applicable to extreme values (see Chapter 14). Building codes for wind loading on structures contain information on estimating extreme wind conditions. For ventilation applications, extreme winds are usually not required, and the 99th percentile limit can be accurately estimated from meteorological station data averaged over less than 10 years.

Table 2 Typical Relationship of Hourly Wind Speed U_{met} to Annual Average Wind Speed U_{annual}

Percentage of Hourly Values That Exceed U_{met}	Wind Speed Ratio U_{met}/U_{annual}
90%	0.2 ± 0.1
75%	0.5 ± 0.1
50%	0.8 ± 0.1
25%	1.2 ± 0.15
10%	1.6 ± 0.2
5%	1.9 ± 0.3
1%	2.5 ± 0.4

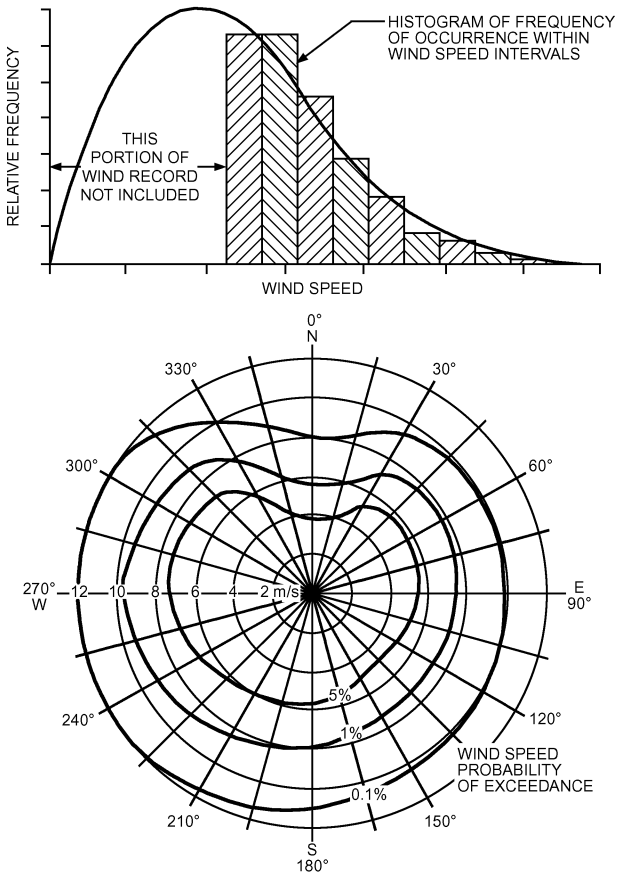

Fig. 14 Frequency Distribution of Wind Speed and Direction

Estimating Wind at Sites Remote from Recording Stations

Many building sites are located far from the nearest long-term wind recording site, which is usually an airport meteorological station. To estimate wind conditions at such sites, the terrain surrounding both the anemometer site and the building site should be checked. In the simplest case of flat or slightly undulating terrain with few obstructions extending for large distances around and between the anemometer site and building site, recorded wind data can be assumed to be representative of that at the building site. Wind direction occurrence frequency at a building site should be inferred from airport data only if the two locations are on the same terrain, with no terrain features that could alter wind direction between them.

In cases where the only significant difference between the anemometer site terrain and the building site terrain is surface roughness, the mean wind speed can be adjusted using Equation (4) and Table 1, to yield approximate wind velocities at the building site. Wind direction frequencies at the site are assumed to be the same as at the recording station.

In using Equation (4), there may be cases where, for a given wind direction, the terrain upwind of either the building or recording site does not fall into just one of the categories in Table 1. The terrain immediately upwind of the site may fall into one category, and that farther upwind fall into a different category. For example, at a downtown airport the terrain may be flat and open (category 3) immediately around the recording instrument, but urban or suburban (category 2) a relatively short distance away. This difference in terrains also occurs when a building or recording site is in an urban area near open water or at the edge of town. In these cases, the suggested approach is to use the terrain category most representative of the average condition within approximately 1.6 km upwind of the site (Deaves 1981). If the average condition is somewhere between two categories described in Table 1, the values of a and δ can be interpolated from those given in the table.

Several other factors are important in causing wind speed and direction at a building site to differ from values recorded at a nearby meteorological station. Wind speeds for buildings on hillcrests or in valleys where the wind is accelerated or channeled can be 1.5 times higher than meteorological station data. Wind speeds for buildings sheltered in the lee of hills and escarpments can be reduced to 0.5 times the values at nearby flat meteorological station terrain.

In more complex terrain, both wind speed and direction may be significantly different from those at the distant recording site. In these cases, building site wind conditions should not be estimated from airport data. Options are either to establish an on-site wind recording station or to commission a detailed wind tunnel correlation study between the building site and long-term meteorological station wind observations.

When wind is calm or light in the rural area surrounding a city, urban air tends to rise in a buoyant plume over the city center. This rising air, heated by anthropogenic sources and higher solar absorption in the city, is replaced by air pushed toward the city center from the edges. In this way, the urban heat island can produce light wind speeds and direction frequencies significantly different than those at a rural meteorological station.

4. WIND EFFECTS ON SYSTEM OPERATION

A building with only upwind openings is positively pressurized because of the wind (Figure 15A). Building pressures are negative when there are only downwind openings (Figure 15B). A building with internal partitions and openings (Figure 15C) is under various pressures, depending on the relative sizes of openings and wind direction. With larger openings on the upwind face, the building interior tends toward positive pressure; the reverse is also true (see Figures 8 to 13, and Chapter 16).

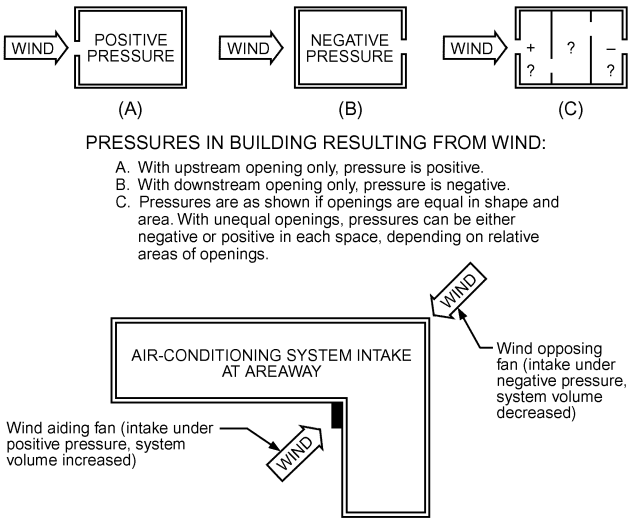

Fig. 15 Sensitivity of System Volume to Locations of Building Openings, Intakes, and Exhausts

With few exceptions, building intakes and exhausts cannot be located or oriented such that a prevailing wind ensures effective ventilation and air-conditioning system operation. Wind can assist or hinder inlet and exhaust fans, depending on their positions on the building, but even in locations with a predominant wind direction, the ventilating system must perform adequately for all other directions. To avoid variable system flow rates, use Figures 8, 9, and 12 as a guide to placing inlets and exhausts in locations where surface pressure coefficients do not vary greatly with wind direction. Also consider the potential for cross contamination; see Chapter 45 of the 2019 *ASHRAE Handbook—HVAC Applications* for details.

Airflow through a wall opening results from differential pressures, which may exceed 125 Pa during high winds. Supply and exhaust systems, openings, dampers, louvers, doors, and windows make building flow conditions too complex for direct calculation. Iterative calculations are required because of the nonlinear dependence of volume flow rate on the differential pressure across an opening. Several multizone airflow models are available for these iterative calculations (Feustel and Dieris 1992; Walton and Dols 2005). Opening and closing of doors and windows by building occupants add further complications. In determining C_p, wind direction is more important than the position of an opening on a wall, as shown in Figures 8 and 9. Refer to Chapter 16 for details on wind effects on building ventilation, including natural and mechanical systems.

Cooling towers and similar equipment should be oriented to take advantage of prevailing wind directions, if possible, based on careful study of meteorological data and flow patterns on the building for the area and time of year.

Natural and Mechanical Ventilation

With natural ventilation, wind may augment, impede, or sometimes reverse the airflow through a building. For flat roof areas with large along-wind sides, wind can reattach to the roof downwind of the leading edge (see Figures 3 and 4). For peaked roofs, the upwind slope may be positively pressurized while the downwind slope may be negatively pressurized, as shown in Figure 12. Thus, any natural ventilation openings could see either a positive or negative pressure, dependent on wind speed and direction. Positive pressure existing where negative pressures were expected could reverse expected natural ventilation. These reversals can be avoided by using stacks,

Licensed for single user. © 2021 ASHRAE, Inc.

continuous roof ventilators, or other exhaust devices in which flow is augmented by wind.

Mechanical ventilation is also affected by wind conditions. A low-pressure wall exhaust fan (12 to 25 Pa) can suffer drastic reduction in capacity. Flow can be reduced or reversed by wind pressure on upwind walls, or increased substantially when subjected to negative pressure on the downwind wall. Side walls may be subjected to either positive or negative pressure, depending on wind direction. Clarke (1967), measuring medium-pressure air-conditioning systems (250 to 370 Pa), found flow rate changes of 25% for wind blowing into intakes on an L-shaped building compared to wind blowing away from intakes. Such changes in flow rate can cause noise at supply outlets and drafts in the space served.

For mechanical systems, wind can be thought of as an additional pressure source in series with a system fan, either assisting or opposing it (Houlihan 1965). Where system stability is essential, supply and exhaust systems must be designed for high pressures (about 750 to 1000 Pa) or use devices to actively minimize unacceptable variations in flow rate. To conserve energy, the selected system pressure should be the minimum consistent with system needs.

Quantitative estimates of wind effects on a mechanical ventilation system can be made by using the pressure coefficients in Figures 8 to 13 to calculate wind pressure on air intakes and exhausts. A simple worst-case estimate is to assume a system with 100% makeup air supplied by a single intake and exhausted from a single outlet. The building is treated as a single zone, with an exhaust-only fan as shown in Figure 16. This overestimates the effect of wind on system volume flow.

Combining Equations (2) and (3), surface wind pressures at air intake and exhaust locations are

$$p_{s\,intake} = C_{p\,intake}\frac{\rho_a U_H^2}{2} \tag{5}$$

$$p_{s\,exhaust} = C_{p\,exhaust}\frac{\rho_a U_H^2}{2} \tag{6}$$

For the single-zone building shown in Figure 16, a worst-case estimate of wind effect neglects any flow resistance in the intake grill and duct, making interior building pressure $p_{interior}$ equal to outdoor wind pressure on the intake ($p_{interior} = p_{s\,intake}$). Then, with all system flow resistance assigned to the exhaust duct in Figure 16, and a pressure rise Δp_{fan} across the fan, pressure drop from outdoor intake to outdoor exhaust yields

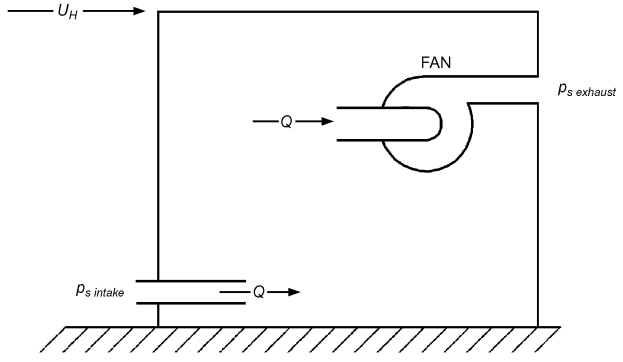

Fig. 16 Intake and Exhaust Pressures on Exhaust Fan in Single-Zone Building

$$(p_{s\,intake} - p_{s\,exhaust}) + \Delta p_{fan} = F_{sys}\frac{\rho Q^2}{A_L^2} \tag{7}$$

where F_{sys} is system flow resistance, A_L is flow leakage area, and Q is system volume flow rate. This result shows that, for the worst-case estimate, the wind-induced pressure difference simply adds to or subtracts from the fan pressure rise. With inlet and exhaust pressures from Equations (5) and (6), the effective fan pressure rise $\Delta p_{fan\,eff}$ is

$$\Delta p_{fan\,eff} = \Delta p_{fan} + \Delta p_{wind} \tag{8}$$

where

$$\Delta p_{wind} = (C_{p\,intake} - C_{p\,exhaust})\frac{\rho_a U_H^2}{2} \tag{9}$$

The fan is wind assisted when $C_{p\,intake} > C_{p\,exhaust}$ and wind opposed when the wind direction changes, causing $C_{p\,intake} < C_{p\,exhaust}$. The effect of wind-assisted and wind-opposed pressure differences is shown in Figure 17.

Example 3. Make a worst-case estimate for the effect of wind on the supply fan for a low-rise building with height H = 15 m, located in a city suburb. Use the hourly average wind speed that will be exceeded only 1% of the time and assume an annual hourly average speed of U_{annual} = 4 m/s measured on a meteorological tower at height H_{met} = 10 m at a nearby airport. Outdoor air density is ρ_a = 1.2 kg/m^3.

Solution: From Table 2, the wind speed exceeded only 1% of the hours each year is a factor of 2.5 ± 0.4 higher than the annual average of 4 m/s, so the 1% maximum speed at the airport meteorological station is

$$U_{met} = 2.5 \times 4 = 10 \text{ m/s}$$

From Example 1, building wind speed U_H is 7.8 m/s.

A worst-case estimate of wind effect must assume intake and exhaust locations on the building that produce the largest difference ($C_{p\,intake} - C_{p\,exhaust}$) in Equations (8) and (9). From Figure 9, the largest difference occurs for the intake on the upwind wall AB and the exhaust on the downwind wall CD, with a wind angle $\theta_{AB} = 0°$. For this worst case, $C_{p\,intake}$ = +0.8 on the upwind wall and $C_{p\,exhaust}$ = –0.43 on the downwind wall. Using these coefficients in Equations (8) and (9) to evaluate effective fan pressure $\Delta p_{fan\,eff}$,

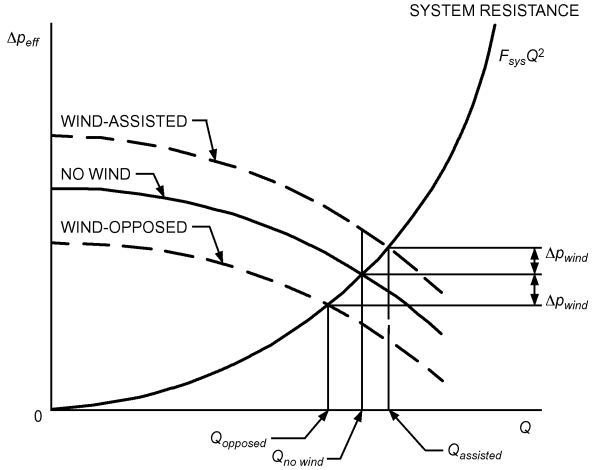

Fig. 17 Effect of Wind-Assisted and Wind-Opposed Flow

Licensed for single user. © 2021 ASHRAE, Inc.

$$\Delta p_{fan\ eff} = \Delta p_{fan} + [0.8 - (-0.43)]\frac{1.2(7.8)^2}{2}$$
$$= \Delta p_{fan} + 44.9 \text{ Pa}$$

This wind-assisted hourly averaged pressure is exceeded only 1% of the time (88 hours per year). When wind direction reverses, the outlet will be on the upwind wall and the inlet on the downwind wall, producing wind-opposed flow, changing the sign from +44.9 to –44.9 Pa. The importance of these pressures depends on their size relative to the fan pressure rise Δp_{fan}, as shown in Figure 17.

Minimizing Wind Effect on System Volume Flow Rate

Wind effect can be reduced by careful selection of inlet and exhaust locations. Because wall surfaces are subject to a wide variety of positive and negative pressures, wall openings should be avoided when possible. When they are required, wall openings should be away from corners formed by building wings (see Figure 15). Mechanical ventilation systems should operate at a pressure high enough to minimize wind effect. Low-pressure systems and propeller exhaust fans should not be used with wall openings unless their ventilation rates are small or they are used in noncritical services (e.g., storage areas).

Although roof air intakes in flow recirculation zones best minimize wind effect on system flow rates, current and future air quality in these zones must be considered. These locations should be avoided if a contamination source exists or may be added in the future. The best area is near the middle of the roof, because the negative pressure there is small and least affected by changes in wind direction (see Figure 12). Consider avoiding edges of the roof and walls, where large pressure fluctuations occur. Either vertical or horizontal (mushroom) openings can be used. On roofs with large areas, where intake may be outside the roof recirculation zone, mushroom or 180° gooseneck designs minimize impact pressure from wind flow. Vertical louvered openings or 135° goosenecks are undesirable for this purpose or for rain protection.

Heated air or contaminants should be exhausted vertically through stacks, above the roof recirculation zone. Horizontal, louvered (45° down), and 135° gooseneck discharges are undesirable, even for heat removal systems, because of their sensitivity to wind effects. A 180° gooseneck for hot-air systems may be undesirable because of air impingement on tar and felt roofs. Vertically discharging stacks in a recirculation region (except near a wall) have the advantage of being subjected only to negative pressure created by wind flow over the tip of the stack. See Chapter 45 of the 2019 *ASHRAE Handbook—HVAC Applications* for information on stack design.

Chemical Hood Operation

Wind effects can interfere with safe chemical hood operation. Supply volume flow rate variations can cause both disturbances at hood faces and a lack of adequate hood makeup air. Volume flow rate surges, caused by fluctuating wind pressures acting on the exhaust system, can cause momentary inadequate hood exhaust. If highly toxic contaminants are involved, surging is unacceptable. The system should be designed to eliminate this condition. On low-pressure exhaust systems, it is impossible to test the hoods under wind-induced, surging conditions. These systems should be tested during calm conditions for safe flow into the hood faces, and rechecked by smoke tests during high wind conditions. For more information on chemical hoods, see Chapter 16 of the 2019 *ASHRAE Handbook—HVAC Applications*. For more information on stack and intake design, see Chapter 45 of that volume.

5. BUILDING PRESSURE BALANCE AND INTERNAL FLOW CONTROL

Proper building pressure balance avoids flow conditions that make doors hard to open and cause drafts. In some cases (e.g., office buildings), pressure balance may be used to prevent confinement of contaminants to specific areas. In other cases (e.g., laboratories), the correct internal airflow is towards the contaminated area.

Pressure Balance

Although supply and exhaust systems in an indoor area may be in nominal balance, wind can upset this balance, not only because of its effects on fan capacity but also by superimposing infiltrated or exfiltrated air (or both). These effects can make it challenging to control environmental conditions. Where building balance and infiltration are important, consider the following:

- Design HVAC system with pressure adequate to minimize wind effects
- Include controls to regulate flow rate, pressure, or both
- Separate supply and exhaust systems to serve each building area requiring control or balance
- Use revolving or other self-closing doors or double-door air locks to noncontrolled adjacent areas, particularly exterior doors
- Seal windows and other leakage sources
- Close natural ventilation openings

Internal Flow Control

Airflow direction is maintained by controlling pressure differentials between spaces. In a laboratory building, for example, peripheral rooms such as offices and conference rooms are kept at positive pressure, and laboratories at negative pressure, both with reference to corridor pressure. Pressure differentials between spaces are normally obtained by balancing supply system airflows in the spaces in conjunction with exhaust systems in the laboratories. Differential pressure instrumentation is normally used to control airflow.

The pressure differential for a room adjacent to a corridor can be controlled using the corridor pressure as the reference. Outdoor pressure cannot usually control pressure differentials within internal spaces, even during periods of relatively constant wind velocity (wind-induced pressure). A single pressure sensor can measure the outdoor pressure at one point only and may not be representative of pressures elsewhere.

Airflow (or pressure) in corridors is sometimes controlled by an outdoor reference probe that senses static pressure at doorways and air intakes. The differential pressure measured between the corridor and the outdoors may then signal a controller to increase or decrease airflow to (or pressure in) the corridor. Unfortunately, it is difficult to locate an external probe where it will sense the proper external static pressure. High wind velocity and resulting pressure changes around entrances can cause great variations in pressure.

To measure ambient static pressure, the probe should be located where airflow streamlines are not affected by the building or nearby buildings. One possibility is at a height of 1.5*R*, as shown in Figure 18. However, this is usually not feasible. If an internal space is to be pressurized relative to ambient conditions, the pressure must be known on each exterior surface in contact with the space. For example, a room at the northeast corner of the building should be pressurized with respect to pressure on both the north and east building faces, and possibly the roof. In some cases, multiple probes on a single building face may be required. Figures 8 to 12 may be used as guides in locating external pressure probes. System volume and pressure control is described in Chapter 45 of the 2019 *ASHRAE Handbook—HVAC Applications*.

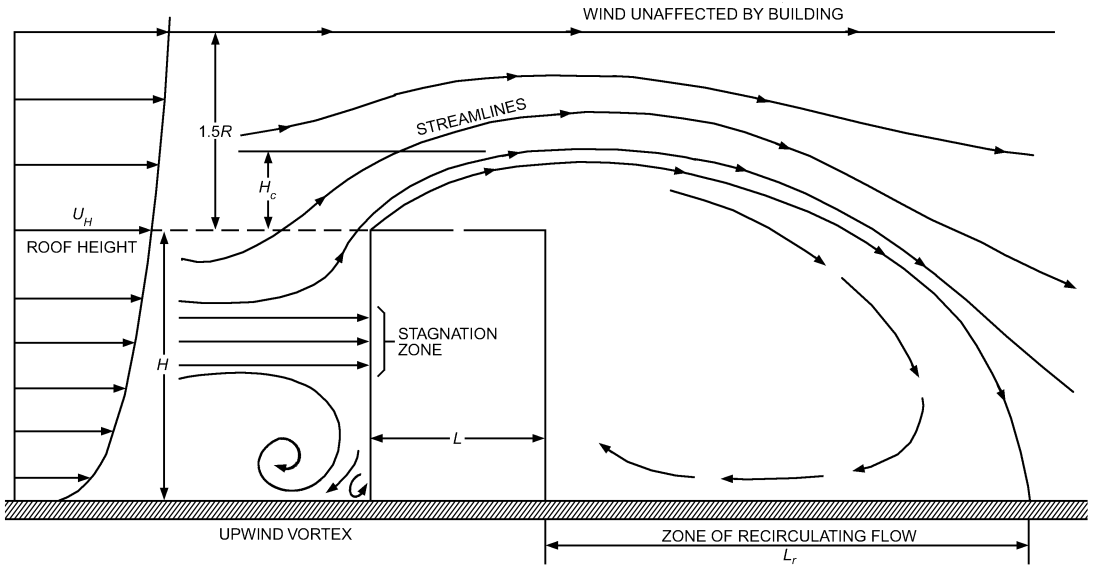

Fig. 18 Flow Patterns Around Rectangular Block Building
(modified from Hosker 1984)

6. ENVIRONMENTAL IMPACTS OF BUILDING EXTERNAL FLOW

Pollutant Dispersion and Exhaust Reentrainment

Pollutant dispersion around buildings is highly affected by the complex flow field. Contaminants are not always transported along the approaching flow direction and can be advected windward by reverse flows and retained in wake flows (Huber and Snyder 1982; Li and Meroney 1983; Stathopoulos et al. 2002). Intakes and exhausts should be installed carefully, considering wind direction and roof geometry (e.g., stack height, rooftop structures) to avoid air intake contamination and exhaust reentrainment (Gupta et al. 2012; Lazure et al. 2002; Stathopoulos et al. 2004). Empirical guidelines that can be used are given in Chapter 45 of the 2019 *ASHRAE Handbook—HVAC Applications*. More detailed prediction can be done by physical and numerical modeling, as explained in the section on Physical and Computational Modeling. State-of-the-art reviews on modeling of pollutant dispersion were performed by Canepa (2004), Di Sabatino et al. (2013), Lateb et al. (2016), Meroney (2004), and Tominaga and Stathopoulos (2013).

Pedestrian Wind Comfort and Safety

Although thermal comfort is also important [e.g., Metje et al. (2008); Stathopoulos (2006)], wind comfort and safety generally only refer to the mechanical effects of wind on people [e.g., Lawson and Penwarden (1975); Willemsen and Wisse (2007)]. Particularly near high-rise buildings, high wind velocities can occur at pedestrian level that can be uncomfortable or even dangerous. For an isolated high-rise building or one amid low rise buildings, high wind speed at pedestrian level can be caused by the downflow that creates the standing vortex and the corner streams (see Figure 1). For building groups, amplified wind speed can occur in passages through and between buildings. Uncomfortable wind conditions can be detrimental to the success of new buildings. Wise (1970) reported shops that were left untenanted because of the windy environment that discouraged shoppers. Lawson and Penwarden (1975) reported dangerous wind conditions to be responsible for the death of two elderly women who were blown over by sudden wind gusts near a high-rise building. Many current urban authorities recognize the importance of pedestrian wind comfort and wind safety, and require studies before granting building permits for new buildings or new urban areas. ASCE (2004) documented the state of the art of outdoor human comfort and its assessment. The first standard on wind comfort and wind safety was developed in the Netherlands and published in 2006 (NEN *Standard* 8100; Willemsen and Wisse 2007) and applied in several published case studies [e.g., Blocken et al. (2012)]. Reviews on studies of pedestrian wind comfort and safety were provided by Blocken (2014), Blocken and Stathopoulos (2013), Blocken et al. (2016), Mochida and Lun (2008), and Stathopoulos (2006). Although laser Doppler anemometry, particle image velocimetry, and large-eddy simulation (LES) are inherently more accurate techniques, Blocken et al. (2016) recommended faster and less expensive techniques for pedestrian-level wind (PLW) studies, such as hot-wire anemometry, Irwin probes, or steady Reynolds-averaged Navier-Stokes computational fluid dynamics (RANS CFD) simulations. The reason is that their lower accuracy at lower amplification factors does not necessarily compromise the accuracy of PLW comfort assessment, because the higher amplification factors provide the largest contribution to the discomfort exceedance probability in the comfort criterion.

Wind-Driven Rain on Buildings

Wind-driven rain (WDR), also called **driving rain,** is one of the most important moisture sources for building facades. It is an essential boundary condition for the analysis of the hygrothermal behavior and durability of historical and contemporary building facade components (Blocken and Carmeliet 2004; Dalgliesh and Surry 2003; Masters et al. 2008; Sanders 1996; Tang et al. 2004).

Wind-driven rain can be assessed by full-scale measurements, wind tunnel measurements, semiempirical formulas, or numerical simulation with CFD. The experimental methods consist of measuring WDR with WDR gages. However, for practical purposes, measurements are generally time consuming, expensive, and often impractical. Blocken and Carmeliet (2006) and Högberg et al. (1999) found that WDR measurements are very prone to error. In addition, measurements made on facades of a particular building at a particular site have limited applicability to facades of other buildings at other sites. This awareness has led researchers to develop calculation models, which have been progressively improved throughout the years. Today, the most advanced and most frequently used models are the semiempirical model in ISO *Standard* 15927-3 (ISO model), the semiempirical model by Straube (1998) and

Licensed for single user. © 2021 ASHRAE, Inc.

Straube and Burnett (2000) (SB model), and the CFD model by Choi (1991, 1993, 1994) extended into the time domain by Blocken and Carmeliet (2002). State-of-the-art reviews on the assessment of WDR on building facades were provided by ASCE (2014) and Blocken and Carmeliet (2004, 2010).

7. PHYSICAL AND COMPUTATIONAL MODELING

For many routine design applications, flow patterns and wind pressures can be estimated using the data and equations presented in the previous sections. Exhaust dilution for simple building geometries in homogeneous terrain environments (e.g., no larger buildings or terrain features nearby) can be estimated using the data and equations presented in the previous sections and in Chapter 45 of the 2019 *ASHRAE Handbook—HVAC Applications*. However, in critical applications, such as where health and safety are of concern, more accurate estimates may be required.

Physical Modeling

Measurements on small-scale models in wind tunnels or water channels can provide information for design before construction. These measurements can also be used as an economical method of performance evaluation for existing facilities. Full-scale testing is not generally useful in the initial design phase because of the time and expense required to obtain meaningful information, but it is useful for verifying data derived from physical modeling and for planning remedial changes to improve existing facilities (Cochran 2006).

Detailed accounts of physical modeling, field measurements and applications, and engineering problems resulting from atmospheric flow around buildings are available in international journals, proceedings of conferences, and research reports on wind engineering (see the Bibliography).

The wind tunnel is the main tool used to assess and understand airflow around buildings. Water channels or tanks can also be used, but are more difficult to implement and give only qualitative results for some cases. Models of buildings, complexes, and the local surrounding topography are constructed and tested in a simulated turbulent atmospheric boundary layer. Airflow, wind pressures, snow loads, structural response, or pollutant concentrations can then be measured directly by properly scaling wind, building geometry, and exhaust flow characteristics. Wind tunnel studies of natural ventilation are particularly suitable for buildings with large openings that provide a strong coupling between outdoor wind flow and indoor airflow (Karava et al. 2011; Kato et al. 1992). Dalgliesh (1975) and Petersen (1987a) found generally good agreement between the results of wind tunnel simulations and corresponding full-scale data. Cochran (1992) and Cochran and Cermak (1992) found good agreement between model and full-scale measurements of low-rise architectural aerodynamics and cladding pressures, respectively. Stathopoulos et al. (1999, 2002, 2004) obtained good agreement between model and full-scale measurements of the dispersion of gaseous pollutants from rooftop stacks on two different buildings in an urban environment.

Similarity Requirements

Physical modeling is most appropriate for applications involving small-scale atmospheric motions, such as recirculation of exhaust downwind of a laboratory, wind loads on structures, wind speeds around building clusters, snow loads on roofs, and airflow over hills or other terrain features. Winds associated with tornadoes, thunderstorms, and large-scale atmospheric motion cannot currently be physically modeled accurately, although the physical modeling of tornadoes and thunderstorm downbursts is a current topic of significant research.

Snyder (1981) gives guidelines for fluid modeling of atmospheric diffusion. This report contains explicit directions and should be used whenever designing wind tunnel studies to assess concentration levels of air pollutants. ASCE *Standard* 7, ASCE *Manual of Practice* 67 (ASCE 1999), and AWES *Quality Assurance Manual* (AWES 2001) also provide guidance when wind tunnels are used for evaluating wind effects on structures.

A complete and exact simulation of airflow over buildings and the resulting concentration or pressure distributions cannot be achieved in a physical model. However, this is not a serious limitation. Cermak (1971, 1975, 1976a, 1976b), Petersen (1987a, 1987b), and Snyder (1981) found that transport and dispersion of laboratory exhaust can be modeled accurately if the following criteria are met in the model and full scale:

1. Match exhaust velocity to wind speed ratios, V_e/U_H.
2. Match exhaust to ambient air density ratios, ρ_e/ρ_a.
3. Match exhaust Froude numbers. $Fr^2 = \rho_a V_e^2/[(\rho_e - \rho_a)gd]$, where d is effective exhaust stack diameter.
4. Ensure fully turbulent stack gas flow by ensuring stack flow Reynolds number ($Re_s = V_e d/\nu$) is greater than 2000 [where ν is the kinematic viscosity of ambient (outdoor) air], or by placing an obstruction inside the stack to enhance turbulence.
5. Ensure fully turbulent wind flow.
6. Scale all dimensions and roughness by a common factor.
7. Match atmospheric stability by the bulk Richardson number (Cermak 1975). For most applications related to airflow around buildings, neutral stratification is assumed, and no Richardson number matching is required.
8. Match mean velocity and turbulence distributions in the wind.
9. Ensure building wind Reynolds number ($Re_b = U_H R/\nu$) is greater than 11 000 for sharp-edged structures, or greater than 90 000 for round-edged structures.
10. Ensure less than 5% blockage of wind tunnel cross section.

For wind speeds, flow patterns, or pressure distributions around buildings, only conditions 5 to 10 are necessary. Usually, each wind tunnel study requires a detailed assessment to determine the appropriate parameters to match in the model and full scale.

In wind tunnel simulations of exhaust gas recirculation, buoyancy of the exhaust gas (condition 3) is often not modeled. This allows using a high wind tunnel speed or a smaller model to achieve high enough Reynolds numbers (conditions 4, 5, and 9). Neglecting buoyancy is justified if density of building exhaust air is within 10% of the ambient (outdoor) air. Also, critical minimum dilution D_{crit} occurs generally at wind speeds high enough to produce a well-mixed, neutrally stable atmosphere, allowing stability matching (condition 7) to be neglected (see Chapter 45 of the 2019 *ASHRAE Handbook—HVAC Applications* for discussion of D_{crit}). However, in some cases and depending on emission sources, calm conditions may produce critical dilution. Nevertheless, omission of conditions 3 and 7 simplifies the test procedure considerably, reducing both testing time and cost.

Buoyancy should be properly simulated for high-temperature exhausts such as boilers and diesel generators. Equality of model and prototype Froude numbers (condition 3) requires tunnel speeds of less than 0.5 m/s for testing. However, greater tunnel speeds may be needed to meet the minimum building Reynolds number requirement (condition 4).

Wind Simulation Facilities

Boundary-layer wind tunnels are required for conducting most wind studies. The wind tunnel test section should be long enough to establish, upwind of the model building, a deep boundary layer that slowly changes with downwind distance.

Other important wind tunnel characteristics include width and height of the test section, range of wind speeds, roof adjustability,

Licensed for single user. © 2021 ASHRAE, Inc.

and temperature control. Larger models can be used in tunnels that are wider and taller, which, in turn, give better measurement resolution. Model blockage effects can be minimized by an adjustable roof height. Temperature control of the tunnel surface and airflow is required when atmospheric conditions other than neutral stability are to be simulated. Boundary-layer characteristics appropriate for the site are established by using roughness elements on the tunnel floor that produce mean velocity, turbulence intensity profiles, and spectra characteristic of full scale.

Water can also be used for the modeling fluid if an appropriate flow facility is available. Flow facilities may be in the form of a tunnel, tank, or open channel. Water tanks with a free surface ranging in size up to that of a wind tunnel test section have been used by towing a model (upside down) through the nonflowing fluid. Stable stratification can be obtained by adding a salt solution. This technique does not allow development of a boundary layer and therefore yields only approximate, qualitative information on flow around buildings. Water channels can be designed to develop thick, turbulent boundary layers similar to those developed in the wind tunnel. One advantage of such a flow system is ease of flow visualization, but this is offset by a greater difficulty in developing the correct turbulence structure and the measurement of flow variables and concentrations.

Designing Model Test Programs

The first step in planning a test program is selecting the model length scale. This choice depends on cross-sectional dimensions of the test section, dimensions of the buildings to be modeled, and/or topographic features and thickness of the simulated atmospheric boundary layer. Typical geometric scales range from about 120:1 to 1000:1.

Because a large model is desirable to meet minimum Reynolds and Froude number requirements, a wide test section is advantageous. In general, the model at any section should be small compared to the test section area so that blockage is less than 5% (Melbourne 1982).

The test program must include specifications of the meteorological variables to be considered (e.g., wind direction, wind speed, thermal stability). Data taken at the nearest meteorological station should be reviewed to obtain a realistic assessment of wind climate for a particular site. Ordinarily, local winds around a building, pressures, and/or concentrations are measured for 16 wind directions (e.g., 22.5° intervals). This is easily accomplished by mounting the building model and its nearby surroundings on a turntable. More than 16 wind directions are required for highly toxic exhausts or for finding peak fluctuating pressures on a building. If only local wind information and pressures are of interest, testing at one wind speed with neutral stability is sufficient.

Computational Modeling

Computational fluid dynamics (CFD) models attempt to resolve airflow around buildings by solving the Navier-Stokes equations or an approximate form of these equations in discretized form. The potential for computational wind engineering (CWE) has increased tremendously in the past decades. Nevertheless, there are some topics for which CWE in its current stage remains inappropriate.

According to Stathopoulos (2000, 2002), there is great potential for CWE, but the numerical wind tunnel "is still virtual rather than real." According to Murakami (2000), CWE has become a more popular tool, but results usually include numerical errors and prediction inaccuracies. According to a review by Blocken (2014), since 1960, computational wind engineering (CWE) has undergone a successful transition from an emerging field into an increasingly established field in wind engineering research, practice, and education, and its application has continued to spread to a very large range of topics, from pedestrian wind conditions to natural ventilation to pollutant dispersion around buildings. However, in line with the reviews by Stathopoulos (1997, 2000, 2002), it is clear that the largest potential of CWE is still in the field of environmental wind engineering rather than structural wind engineering. Indeed, although CWE can adequately provide mean values of variables for pedestrian wind comfort and wind safety, natural ventilation, or wind-driven rain studies, correct prediction of peak values for wind loading studies, for example, remains very difficult.

Methods for predicting turbulent flow around buildings include the following.

Direct numerical simulation (DNS) directly resolves all the spatial and temporal scales in the flow based on the exact Navier-Stokes equations. This requires very extensive computational resources (runs lasting from several hours to days, depending on computer characteristics, power, and capacity) and can at present only be applied for flow in simple geometries and at low Reynolds numbers (Re). For complex, high-Re flows in wind engineering, application of DNS will not be possible in the foreseeable future.

Large eddy simulation (LES) is a simplified method in which the spatially filtered Navier-Stokes equations are solved. Turbulent structures larger than the filter (sometimes taken equal to the grid size) are explicitly solved, whereas those smaller than the filter are modeled (i.e., approximated) by a subfilter model. Information on filtering and subfilter models can be found in Ferziger and Peric (2002), Geurts (2003), and Meyers et al. (2008).

In **Reynolds-averaged Navier-Stokes (RANS) simulation,** the equations are obtained by averaging the Navier-Stokes equations (time-averaging if the flow is statistically steady, or ensemble-averaging for time-dependent flows). With RANS, only the mean flow is solved, whereas all scales of turbulence must be modeled. Averaging generates additional unknowns for which turbulence models are required. Many turbulence models are available, but no single turbulence model is universally accepted as being the best for all types of applications.

In addition, hybrid RANS/LES approaches are available, in which **unsteady RANS (URANS)** is used near the wall, and LES in the rest of the flow field. This avoids the excessively high near-wall grid resolution required for application of LES near walls in high-Re flow problems. An example of a hybrid RANS/LES approach is **detached eddy simulation (DES)**, as proposed by Spalart et al. (1997).

The statistically steady RANS method is the most widely applied and validated in CWE. It has been used for a wide range of building applications, including estimating pressure coefficients (Meroney et al. 2002; Murakami et al. 1992; Oliveira and Younis 2000; Richards and Hoxey 1992; Stathopoulos 1997; Stathopoulos and Zhou 1993), natural ventilation (Chen 2009; Evola and Popov 2006; Kato et al. 1997; Norton et al. 2009; Ramponi and Blocken 2012; van Hooff and Blocken 2010), wind-driven rain (Blocken and Carmeliet 2004; 2010; Choi 1993, 1994; Tang and Davidson 2004), pollutant dispersion (Cowan et al. 1997; Dawson et al. 1991; Gousseau et al. 2011; Leitl et al. 1997; Li and Stathopoulos 1997; Meroney 2004; Meroney et al. 1999; Tominaga and Stathopoulos 2010, 2011, 2013), pedestrian wind conditions (Blocken et al. 2008, 2012; Richards et al. 2002; Stathopoulos and Baskaran 1996; Yoshie et al. 2007), snow drift (Sundsbo 1998; Thiis 2000; Tominaga and Mochida 1999), and cooling tower drift (Meroney 2006, 2008). Although many past applications of RANS have been limited to isolated buildings or relatively simple building arrangements, large and sometimes very large discrepancies have been found in comparisons with wind tunnel and full-scale measurements. These are at least partly attributed to turbulence model limitations and to the statistically steady solution of flows that exhibit pronounced transient features, such as intermittent separation, recirculation zones, and vortex shedding [e.g., Murakami (1993), Tominaga et al. (2008a)]. In addition, a wide range of other computational aspects can contribute to uncer-

Licensed for single user. © 2021 ASHRAE, Inc.

tainties and errors, divided by COST 732 (Franke et al. 2007) into two broad categories: physical and numerical. **Physical modeling errors** and uncertainties result from assumptions and approximations made in the mathematical description of the physical process. Examples are simplifications of the actual physical complexity (e.g., using RANS instead of DNS) and uncertainties and/or simplifications of the geometric and physical boundary conditions. **Numerical errors** and uncertainties are the result of the numerical solution of the mathematical model. Examples are computer programming errors, computer round-off errors, spatial and temporal discretization errors, and iterative convergence errors.

LES is a time-dependent approach in which more of the turbulence is resolved. It therefore has a larger potential to provide accurate results than statistically steady RANS simulations (Murakami et al. 1992; Tominaga et al. 1997). LES also provides more information about the flow, such as instantaneous and peak wind speeds, pressures, and pollutant concentrations. However, it requires considerably higher CPU times and memory than RANS. It also requires time- and space-resolved data as boundary conditions to properly simulate inflow. Such experimental data are rarely available in practice (Franke et al. 2007). LES is also considered to require more experience for users to apply effectively than does RANS. Several studies have compared RANS and LES modeling for atmospheric dispersion for generic configurations such as isolated buildings (Tominaga and Stathopoulos 2010) and street canyons (Salim et al. 2011; Tominaga and Stathopoulos 2011) and for actual urban environments (Gousseau et al. 2011; Hanna et al. 2006), where LES is shown to consistently outperform steady RANS modeling. However, the drawbacks of LES imply that the practical application of CWE will continue to be mainly based on statistically steady RANS for a considerable while.

Guidelines for using CFD have been developed and assembled to help users avoid, reduce, and estimate errors and uncertainties in applying CFD. ERCOFTAC (2000) provides extensive guidelines for industrial CFD applications, many of which are also applicable to CWE. Franke et al. (2007) assembled a comprehensive best-practice guideline document for CFD simulation of flows in the urban environment. Important guidelines for application of CFD to pedestrian wind conditions around buildings and for predicting wind loads on buildings have been developed by the Architectural Institute of Japan and reported by Mochida et al. (2002), Tamura et al. (2008), Tominaga et al. (2008b), and Yoshie et al. (2007). A set of ten tips and tricks for CFD simulations in urban physics has been provided by Blocken (2015). Other efforts have focused on specific problems, such as those encountered in simulating equilibrium atmospheric boundary layers in computational domains [e.g., Balogh and Parente (2015); Blocken et al. (2007a, 2007b); Gorlé et al. (2009); Hargreaves and Wright (2007); Parente et al. (2011); Richards and Hoxey (1993); Richards and Norris (2011, 2015); Yang et al. (2008)]. Most of these guidelines apply to statistically steady RANS simulations.

Regardless of whether RANS or LES is used, evaluating the accuracy of CFD results by comparing them with wind tunnel or field experiments is very important because turbulence models are based on assumptions; no turbulence model is universally valid for all applications. Physical modeling therefore remains an indispensable tool in (computational) wind engineering.

8. SYMBOLS

a = exponent in power law wind speed profile for local building terrain, Equation (4) and Table 1, dimensionless
A_L = flow leakage area, Equation (7), m^2
a_{met} = exponent a for the meteorological station, Equation (4) and Table 1, dimensionless
B_L = larger of two upwind building face dimensions H and W, Equation (1), m
B_s = smaller of two upwind building face dimensions H and W, Equation (1), m
C_p = local wind pressure coefficient for building surface, Equation (3), dimensionless
C_s = surface-averaged pressure coefficient, Figure 6, dimensionless
d = effective stack diameter, m
D_{crit} = critical dilution factor at roof level for uncapped vertical exhaust at critical wind speed (see Chapter 45 of the 2019 *ASHRAE Handbook—HVAC Applications*), dimensionless
Fr = Froude number, dimensionless
F_{sys} = system flow resistance, Equation (7), dimensionless
g = acceleration of gravity, 9.8 m/s^2
H = wall height above ground on upwind building face, Equation (4) and Figure 3, m
H_c = maximum height above roof level of upwind roof edge flow recirculation zone, Figure 4, m
H_{met} = height of anemometer at meteorological station, Equation (4), m
h_s = exhaust stack height (typically above roof unless otherwise specified, m (see Chapter 45 in the 2019 *ASHRAE Handbook—HVAC Applications*)
L = length of building in wind direction, Figure 3, m
L_c = length of upwind roof edge recirculation zone, Figure 4, m
L_r = length of flow recirculation zone behind rooftop obstacle or building, Figure 4, m
p_s = wind pressure difference between exterior building surface and local ambient (outdoor) atmospheric pressure at same elevation in undisturbed approach wind, Equation (3), Pa
p_v = wind velocity pressure at roof level, Equation (2), Pa
Q = volumetric flow rate, Equation (7), m^3/s
R = scaling length for roof flow patterns, Equation (1), m
Re_b = building Reynolds number, dimensionless
Re_s = stack flow Reynolds number, dimensionless
S = stretched-string distance; shortest distance from exhaust to intake over obstacles and along building surface, m (see Chapter 45 in the 2019 *ASHRAE Handbook—HVAC Applications*)
U_{annual} = annual average of hourly wind speeds U_{met}, Table 2, m/s
U_H = mean wind speed at height H of upwind wall in undisturbed flow approaching building, Equation (2) and Figure 4, m/s
U_{met} = meteorological station hourly wind speed, measured at height H_{met} above ground in smooth terrain, Equation (4) and Table 2, m/s
V_e = exhaust face velocity, m/s
W = width of upwind building face, Figure 3, m

Greek

δ = fully developed atmospheric boundary layer thickness, Equation (4) and Table 1, m
δ_{met} = atmospheric boundary layer thickness at meteorological station, Equation (4) and Table 1, m
Δp_{fan} = pressure rise across fan, Equation (7), Pa
$\Delta p_{fan\,eff}$ = effective pressure rise across fan, Equation (8), Pa
Δp_{wind} = wind-induced pressure, Equations (8) and (9), Pa
θ = angle between perpendicular line from upwind building face and wind direction, Figures 8 to 12, degrees
ν = kinematic viscosity of ambient (outdoor) air, m^2/s
ρ_a = ambient (outdoor) air density, Equation (2), kg/m^3
ρ_e = density of exhaust gas mixture, kg/m^3

Criteria to Evaluate Hygrothermal Simulation Results 25.16

PROPER design of space heating, cooling, and air-conditioning systems requires detailed knowledge of the building envelope's overall heat, air, and moisture performance. This chapter discusses the fundamentals of combined heat, air, and moisture movement as it relates to the analysis and design of envelope assemblies. Guidance for designing mechanical systems is found in other chapters of the *ASHRAE Handbook*.

Because heat, air, and moisture transfer are coupled and interact closely with each other, they should not be treated separately. For example, improving a building envelope's energy performance may cause moisture-related problems. Conversely, evaporation of water and removal of moisture by other means are processes that require energy. Only a sophisticated moisture control strategy can ensure hygienic conditions and adequate durability for modern, energy-efficient building assemblies. Effective moisture control design must deal with all **hygrothermal** (heat and humidity) loads acting on the building envelope.

1. FUNDAMENTALS

1.1 TERMINOLOGY AND SYMBOLS

The following heat, air, and moisture definitions, properties, and symbols are commonly used.

A **building envelope** or **building enclosure** provides physical separation between the indoor space and the outdoor environment. A **building assembly** is any part of the building envelope, such as a wall, window, or roof assembly, that faces the interior and exterior of the building. A **building component** is any element, layer, or material within a building assembly.

Heat

Specific heat capacity c is the change in heat (energy) of a unit mass of material for a unit change of temperature in J/(kg·K).

Volumetric heat capacity ρc is the change in heat stored in a unit volume of material for a unit change of temperature, in J/(m^3·K).

Heat flux q, a vector, is the time rate of heat transfer through a unit area, in the direction perpendicular to that area, in W/m^2.

Thermal conductivity k [in Europe, the Greek letter λ (lambda) is used] is a material property describing ability to conduct heat, and is defined by Fourier's law of heat conduction. Thermal conductivity is the property that describes heat flux through a unit thickness of a material in a direction perpendicular to the isothermal planes, induced by a unit temperature difference. (ASTM *Standard* C168 defines homogeneity.) Units are W/(m·K). For anisotropic materials, the direction of heat flux in the material must be noted. Thermal conductivity must be evaluated for a specific mean temperature, thickness, age, and moisture content. Thermal conductivity is normally considered an intrinsic property of a homogenous material. In porous materials, heat flow occurs by a combination of conduction, convection, and radiation, and may depend on orientation, direction, or both. When nonconductive modes of heat transfer occur within the specimen or the test specimen is nonhomogeneous, the measured property of such materials is called **apparent thermal conductivity**. The specific test conditions (e.g., sample thickness, orientation, environment, environmental pressure, surface temperature, mean temperature, temperature difference, moisture distribution) should be reported with the values of apparent thermal conductivity. The symbol k_{app} (or λ_{app}) is used to denote the absence of pure conduction or to indicate that all values reported are apparent. Materials with a low apparent thermal conductivity are called **insulation** materials (see Chapter 26 for more detail).

Thermal resistivity r_u is the reciprocal of thermal conductivity. Units are (m·K)/W.

Thermal resistance R is an extrinsic property that describes the resistance of a material layer or assembly to heat transfer. It is determined by the steady-state or time-averaged temperature difference (between two defined surfaces of a material layer within a building assembly) that induces a unit heat flux, in (m^2·K)/W. When the two defined surfaces have unequal areas, as with heat flux through material layers of nonuniform thickness, an appropriate mean area and mean thickness must be given. Thermal resistance formulas involving materials that are not uniform slabs must contain shape factors to account for the area variation involved. When heat flux occurs by conduction alone, the thermal resistance of a layer of constant thickness may be obtained by dividing the material's thickness by its thermal conductivity. When several modes of heat transfer are involved, the **apparent thermal resistance** may be obtained by dividing the material's thickness by its apparent thermal conductivity. When air circulates within or passes through insulation, as may happen in low-density fibrous materials, the apparent thermal resistance is affected. Thermal resistances of common building and insulation materials are listed in Chapter 26.

Thermal conductance C is the reciprocal of thermal resistance. Units are W/(m^2·K).

Heat transfer or **surface film coefficient** h is the value that describes the total heat flux by both convection and radiation between a surface and the surrounding environment. It is defined as the heat transfer per unit time and unit area induced by a unit temperature difference between the surface and the reference temperature in the surrounding environment. Units are W/(m^2·K). For convection to

The preparation of this chapter is assigned to TC 4.4, Building Materials and Building Envelope Performance.

occur, the surrounding space must be filled with a fluid, usually air. If the space is evacuated, heat flow occurs by radiation only. In the context of this discussion, **indoor** or **outdoor heat transfer** or **surface film coefficient** h_i or h_o relates to an interior or exterior surface of a building envelope assembly. The heat transfer film coefficient is also commonly known as the **surface film conductance.**

Thermal transmittance U is the quantity equal to the steady-state or time-averaged heat flux from the environment on the one side of a body to the environment on the other side, per unit temperature difference between the two environments, in $W/(m^2 \cdot K)$. Thermal transmittance is sometimes called the **overall coefficient of heat transfer** or **U-factor**. Average thermal transmittance differs from clear-wall transmittance, in that the former considers all thermal bridge effects in the assembly.

Thermal emissivity is the ratio of radiant flux emitted by a surface to that emitted by a black surface at the same temperature. Emissivity refers to intrinsic properties of a material's surface and is defined only for a specimen of the material that is thick enough to be completely opaque and has an optically smooth surface.

Effective emittance E refers to the properties of a particular object. It depends on surface layer thickness, oxidation, roughness, etc.

Air

Air transfer M_a is the time rate of mass transfer by airflow induced by an air pressure difference, caused by wind, stack effect, or mechanical systems, in kg/s.

Air flux m_a, a vector, is the air transfer through a unit area in the direction perpendicular to that unit area, in $kg/(s \cdot m^2)$.

Air permeability k_a is an intrinsic property of a porous material defined by Darcy's Law (the equation for laminar flow through porous materials). Air permeability is the quantity of air flux induced by a unit air pressure difference through a unit thickness of homogeneous porous material in the direction perpendicular to the isobaric planes. Units are in $kg/(Pa \cdot s \cdot m)$ or s.

Air permeance K_a is the extrinsic quantity equivalent to the time rate of steady-state air transfer through a unit surface of a porous membrane or layer, a unit length of joint or crack, or a local leak induced by a unit air pressure difference over that layer, joint and crack, or local leak. Units are $kg/(Pa \cdot s \cdot m^2)$ for a layer, $kg/(Pa \cdot s \cdot m)$ for a joint or crack, or $kg/(Pa \cdot s)$ for a local leak.

Moisture

Moisture content w is the amount of moisture per unit volume of porous material, in kg/m^3.

Moisture ratio X (in mass) or Ψ (in volume) is the amount of moisture per unit mass of dry porous material or the volume of moisture per unit volume of dry material, in percent.

Specific moisture content is the ratio between a change in moisture content and the corresponding change in driving potential (i.e., relative humidity or suction).

Specific moisture ratio is the ratio between a change in moisture ratio and the corresponding change in driving potential (i.e., relative humidity or suction).

Water vapor flux m_v, a vector, is the time rate of water vapor transfer through a unit area in the direction perpendicular to that unit area, in $kg/(s \cdot m^2)$.

Moisture transfer M_m is the moisture flow induced by a difference in suction or in relative humidity, in kg/s.

Moisture flux m_m, a vector, is the time rate of moisture transfer through a unit area in the direction perpendicular to that unit area, in $kg/(s \cdot m^2)$.

Water vapor permeability μ_p is the steady-state water vapor flux through a unit thickness of homogeneous material in a direction perpendicular to the isobaric planes, induced by a unit partial water vapor pressure difference, under specified conditions of temperature and relative humidity. Units are $kg/(Pa \cdot s \cdot m)$. When permeability varies with psychrometric conditions, the specific permeability defines the property at a specific condition.

Water vapor permeance M is the steady-state water vapor flux by diffusion through a unit area of a flat layer, induced by a unit partial water vapor pressure difference across that layer, in $kg/(Pa \cdot s \cdot m^2)$.

Water vapor resistance Z is the reciprocal of water vapor permeance, in $(m^2 \cdot s \cdot Pa)/kg$.

Moisture permeability k_m is the steady-state moisture flux through a unit thickness of a homogeneous material in a direction perpendicular to the isosuction planes, induced by a unit difference in suction. Units are $kg/(Pa \cdot s \cdot m)$ (suction).

Moisture diffusivity D_m is the ratio between the moisture permeability and the specific moisture content, in m^2/s.

1.2 HYGROTHERMAL LOADS AND DRIVING FORCES

This section describes the hygrothermal loads acting on the building envelope. That description is used to predict the influence on the hygrothermal behavior of building assemblies, as a basis for design recommendations and moisture control measures (Künzel and Karagiozis 2004). Cooling and heating load estimations for sizing mechanical systems can be found in Chapters 17 and 18.

In Figure 1, the loads relevant for building envelope design are presented schematically for an external wall. Generally, they show diurnal and seasonal variations at the exterior surface and mainly seasonal variations at the interior surface. In sunny weather, the exterior wall surface heats by solar radiation, leading to evaporation of moisture from the surface layer. Around sunset, when solar radiation decreases, long-wave (infrared) emission to the clear sky may lead to cooling of the exterior surface below the ambient air temperature, even below the dew-point temperature, so surface condensation may occur. This phenomenon is called **undercooling**. The exterior surfaces are also exposed to moisture from precipitation and wind-driven rain.

Usually, several load cycles overlap (e.g., summer/winter, day/night, rain/sun). Therefore, a precise analysis of the expected loads should be done before designing any building envelope component. However, the magnitude of the loads is not independent of building geometry and the component's properties. Analysis of the transient hygrothermal loads is generally based on hourly meteorological

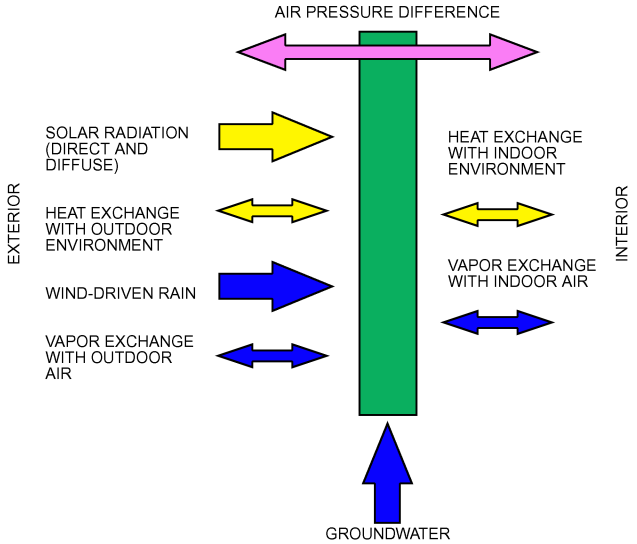

Fig. 1 Hygrothermal Loads and Alternating Diurnal or Seasonal Directions Acting on Building Envelope

Licensed for single user. © 2021 ASHRAE, Inc.

data, although a shorter time step may be needed. However, determination of local conditions at the envelope's surface is complicated and requires specific experience. In some cases, computer simulations are necessary to assess the microclimate acting on differently oriented, overhang-protected, or inclined building assemblies.

Ambient Temperature and Humidity

Ambient temperature and humidity, represented by the partial water vapor pressure, are the boundary conditions always affecting both sides of the building envelope. The climate-dependent exterior conditions may show large diurnal and seasonal variations. Therefore, at least hourly data are required for detailed building simulations, though monthly data may suffice in case simple calculation methods are applicable. Chapter 14 provides such meteorological data sets, including temperature and relative humidity, for many locations worldwide. These data sets usually represent average meteorological years based on long-term observations at specific locations. However, data of more extreme climate conditions may be important to assess the risks of moisture damage. Therefore, Sanders (1996) proposed using data of the coldest or warmest year in 10 years for hygrothermal analysis instead of data from an average year. Another method to obtain a severe annual data set concerning the moisture-related damage risk starting from several decades of hourly data has been developed by Salonvaara (2011). This method analyzes the data with respect to their effect on moisture behavior of typical building assemblies. The more severe data sets increase the safety of risk prediction for the service life of building envelope components, but they are less suitable for analyzing the long-term behavior (performance over several years) of constructions because the probability of a sequence of severe years is very low. Also, note that the temperature at the building site may differ from the meteorological reference data when the site's altitude differs from that of the station recording the data. On average, there is a temperature shift of 0.65 K for every ±100 m. The microclimate around the building may result in an additional temperature shift that depends on the season. For example, the proximity of a lake can moderate seasonal temperature variations, with higher temperatures in winter and lower temperatures in summer compared to sites without water nearby. A low-lying site experiences lower temperatures in winter, whereas city temperatures are higher year round (METEOTEST 2007).

Indoor Temperature and Humidity

Indoor conditions depend on the purpose and occupation of the building. For most commercial constructions, temperature and humidity are controlled by HVAC systems with usually well-defined set points. Indoor humidity conditions in residential buildings, however, are often influenced by the outdoor climate and by occupant behavior. (For details on this highly variable vapor release, see Chapter 37.) That water vapor must be removed by ventilation or air conditioning. The resulting relative humidity may be determined by a hygrothermal whole-building simulation or by simple estimation methods using information on moisture production, air change rates, and climate-dependent HVAC operation (TenWolde and Walker 2001). The presence of spas or swimming pools increases the load substantially. Less obvious but sometimes of equal importance are loads from the ground, from penetrating precipitation, or from construction moisture in the building materials. Moisture loads from occupant behavior show an especially transient pattern: they are characterized by peaks (e.g., cooking, showering). Humidity-buffering envelope materials, partition wall materials, and furniture (e.g., carpets, curtains, paper) help to dampen indoor humidity peaks, but they also reduce the moisture removal efficiency of intermittent ventilation (e.g., periodically opening windows, operating ventilation fans). Information on typical indoor climate conditions of special-purpose constructions such as swimming pools, spas, ice rinks, or agricultural buildings and production plants may be found in the 2019 *ASHRAE Handbook—HVAC Applications*.

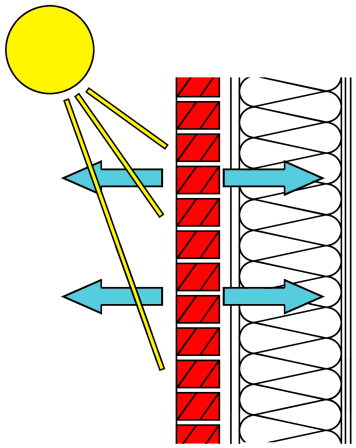

Fig. 2 Solar Vapor Drive and Interstitial Condensation

Solar Radiation

Incident solar radiation is the major thermal load at the building exterior. For direct solar radiation, the resultant irradiation depends on the angle between the sun and the normal on the exposed surface and on its color (short-wave absorptivity). For calculation of incident solar heat flux and spectra, see Chapter 15.

For moisture control, solar radiation is usually considered beneficial. However, in some cases solar radiation combined with water from precipitation or other sources (e.g., construction moisture) can lead to severe moisture problems by solar-driven vapor flow. For example, as shown in Figure 2, if the water-absorbing exterior layer of an assembly (e.g., brick veneer, a typical example of "reservoir" cladding) has been wetted by wind-driven rain, solar irradiation creates such high vapor pressure that, in addition to vapor diffusion toward the outdoors, part of the evaporating water diffuses inwards, leading to condensation on and in material layers within the assembly (e.g., sheathing boards, insulation layers, vapor retarders). Adapting the permeance of vapor retarders and weather-resistive barriers (WRB) to the potential loads may improve the situation. ASHRAE research project RP-1091 (Burnett et al. 2004) showed that cladding ventilation is also an effective remedy within specified exterior air humidity limits.

Exterior Condensation

Long-Wave Radiant Effects. Long-wave radiation exchange of the envelope surface with the cold layers of the lower atmosphere is a major heat transfer process. At night or with the sun at a low angle, it results in a net heat flux to the sky (i.e., heat energy sink) (see Chapter 15). Depending on the building assembly's thermal properties, this may lead to a drop in the envelope's outdoor surface temperature below the ambient air temperature (undercooling). If this surface temperature reaches the air's dew point, condensation occurs on that exterior surface. Massive structures with a high thermal inertia do not usually lose enough heat to the nighttime radiation sink to bring the outdoor surface temperature below the air's dew point for a significant period of time. However, many modern building assemblies, such as lightweight roofs or exterior insulation finish systems (EIFSs), have little thermal inertia in their exterior surface layers and are therefore subject to considerable amounts of exterior condensation (Künzel 2007).

Interior Temperature Differential. Exterior condensation can also occur on poorly insulated assemblies in cooling climates because of the operation of air-conditioning systems. Repeated

Licensed for single user. © 2021 ASHRAE, Inc.

exterior condensation or long-lasting, high relative humidity often provides the basis for soiling or microbial growth (fungi or algae), which may not be acceptable even though the durability of the assembly is unlikely to be affected.

Effect on Other Layers. Under exterior condensation conditions, ventilated assemblies may also experience condensation within the ventilated air layer. This phenomenon was discovered by investigating pitched roofs with cathedral ceiling insulation (Hens 1992; Janssens 1998; Künzel and Grosskinski 1989). However, damage because of condensation in the ventilation plane is rare, except in metal roofs and ventilated low-mass, low-sloped roofs with moisture-sensitive decks (Hens et al. 2007a, 2007b; Zheng et al. 2004). Occasionally, soiling because of condensate runoff has been reported.

Wind-Driven Rain

The load from rain, especially wind-driven rain, is the main reason for moisture-related building failure. Because the requirements of sometimes costly rain-protection measures depend on the local climate, some countries have introduced regional driving-rain classifications. Generally, coastal regions and those on the windward side of mountains receive the highest precipitation load. Areas of low rainfall do not have the potential for severe wind-driven rain.

Regional precipitation and wind are significant factors in determining local wind-driven rain load, but local exposure conditions are of equal importance. A building in an open field receives a higher load than one sheltered by a forest or other buildings. A quantification of exposure conditions for walls depending on landscape, neighborhood, and building size and geometry can be found in the British *Standard* BS 8104 and in the European ISO/DIN *Standard* 15927-3:2006. The average wind-driven rain load R_D in open ground was investigated by Lacy (1965). It is estimated from normal rain R_N and the wind velocity component v parallel to the considered orientation:

$$R_D = fvR_N \quad (1)$$

where

R_D = wind-driven rain intensity, kg/(s·m^2)
f = empirical factor = approximately 0.2 s/m
v = mean wind velocity, m/s
R_N = rain intensity on a horizontal surface in open field, kg/(s·m^2)

Figure 3 shows a "rain rose" of results from Equation (1) plotted in polar coordinates indicating the amount of wind-driven rain in mass per unit area hitting an unobstructed and isolated vertical surface in the open field.

The driving rain load close to a façade is considerably less than in the open field (as shown in Figure 4), and it becomes irregular. Tops and edges of walls generally receive the highest amount. This is caused by the airflow pattern around a building (see Chapter 24 for more information). At the windward side, high pressure gradients coincide with large changes in air velocity. The building acts as an obstacle for the wind, slowing down airflow and subsequently reducing the wind-driven rain load near the façade. Gravity and the rain droplets' momentum prevent them from following the airflow around the building, causing them to strike the façade mainly at the edges of the flow obstacle (Straube and Burnett 2000).

However, the irregular driving rain deposition is often evened out by water running off the hard-hit areas, especially when the façade surface has low water absorptivity or the wind-driven rain load is high enough to capillary-saturate the most exposed surface layers.

Roof overhangs can reduce the driving rain load on low-rise buildings. Slightly inclined wall sections or protruding façade elements may receive a considerable amount of splash water from façade areas above them, in addition to the direct driving rain deposition. This is often a problem for buildings with walls slightly out of vertical (Künzel 2007).

Rain penetrating the exterior cladding of exposed walls may cause severe damage if it cannot be drained and dried out quickly enough. Experience shows that it is almost impossible to seal joints and connections hermetically against wind-driven rain. Therefore, building envelope assemblies should be designed to tolerate a limited amount of water entry (see ASHRAE *Standard* 160-2009).

Construction Moisture

Building damage as a result of migrating construction moisture has become more frequent because tight construction schedules leave little time for building materials to dry. Although often disregarded, construction moisture is either delivered with the building products or absorbed by the materials during storage or construction. Cast-in-place concrete, autoclaved aerated concrete (AAC), calcium silicate brick (CSB), and "green" wood are examples of materials that contain significant volumes of moisture when delivered. Stucco, mortar, clay brick, and concrete blocks are examples of materials that are either mixed or brought into contact with water at the construction site. All other porous building materials may take up considerable amounts of precipitation or groundwater when left unprotected during storage or construction before the enclosure of the building. A single-family house made of AAC may initially contain up to more than 13 Mg of water in its walls.

Care is needed to safely remove that water, either by additional ventilation during the first years of operation or by using construction dryers while heating the building before putting it into service. Even "dry" materials have an initial water content of approximately the equilibrium moisture content at 80% rh (EMC_{80}).When significant construction moisture is encountered, EMC_{80} can be exceeded by a factor of two or more.

Ground- and Surface Water

A high groundwater table or surface water running toward the building and filling the loose fill triangle around the basement represents an important moisture load to the lower parts of the building envelope. These loads should be met by grading the

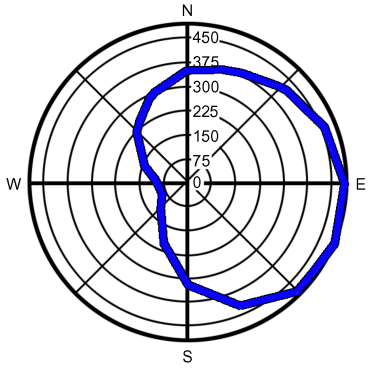

Fig. 3 Typical Wind-Driven Rain Rose for Open Ground

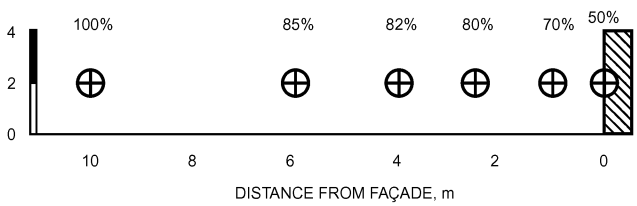

Fig. 4 Measured Reduction in Catch Ratio Close to Façade of One-Story Building at Height of 2 m

Licensed for single user. © 2021 ASHRAE, Inc.

ground away from the building, by perimeter drainage, and by waterproofing the basement and foundation. Instead of waterproofing with bituminous membranes or coatings, water-impermeable structural elements may also be used (e.g., reinforced concrete, which may, however, be vapor permeable). The resulting vapor flux also presents a load that must be addressed (e.g., by basement ventilation). Moisture loads in the ground may impair performance of exterior basement insulation applied on the outside of the waterproofing layer. Therefore, special care must be taken to protect insulation from moisture accumulation unless the insulation material is itself impermeable to water and vapor [e.g., extruded polystyrene (XPS), foam glass].

Wicking of ground- or surface water into porous walls by capillary action is called **rising damp**. This phenomenon may be a sign of poor drainage or waterproofing of the building's basement or foundation. However, other phenomena show moisture patterns similar to rising damp. If the wall is contaminated with salts, which is often the case in historic buildings, the wall's moisture content might stay elevated because of a hygroscopicity increase caused by water uptake by the salt crystals. Another reason for the appearance of rising damp is surface condensation in unheated buildings during summer.

Air Pressure Differentials

Wind, mechanical systems, and stack effects (caused by differences between indoor and outdoor temperature) result in air pressure differentials over the building envelope. In contrast to wind, stack pressure is a constant load that may not be neglected. Worse, pressure differentials may drive airflow in the same direction as vapor pressure: from indoors to outdoors during the heating season, and in the opposite direction during the cooling season. Therefore, airflow through cracks, imperfect joints, or air-permeable assembly layers may cause interstitial condensation in a manner similar to vapor diffusion. However, condensation is likely to be more intense and concentrated around leaks in the building envelope. This can become a problem at the top of a building, which may be especially vulnerable because of discontinuities in the air barrier at the parapets. To avoid moisture damage, airflow through and within the building envelope should be prevented by a continuous air barrier. However, it is difficult to guarantee total airtightness, so the hygrothermal effect of airflow can be important, especially when high pressure differentials are expected (e.g., in multistory or mechanically pressurized buildings). For the practical determination of pressure differentials and airflow, see Chapter 16. Air pressures across the envelope may also drive liquid water inward or outward.

2. HEAT TRANSFER

Heat flow through the building envelope is mainly associated with the building's energy performance. However, other aspects are equally important. Interior surface temperatures not only serve as an indicator for hygienic conditions in the building (e.g., conditions preventing surface condensation or mold growth), but they can also be a major factor for thermal comfort. Temperature peaks and fluctuations within the building envelope or on its surfaces may further affect the envelope's durability. At low temperatures, some building materials tend to become less elastic and sometimes brittle, making them vulnerable to strain or mechanical impact. At high temperatures, some materials degrade because of chemical reactions or irreversible deformation. Deformation and local mechanical failure can also occur under the influence of steep temperature gradients or transients. Whereas some of these aspects can be assessed by steady-state calculations (e.g., heating energy losses, energy end use), others require transient simulations for accurate evaluation.

As explained in Chapter 4, heat transfer by apparent conduction in a solid is governed by Fourier's law:

$$q = -k\,\mathrm{grad}(t) = -\left(k_x\frac{\partial t}{\partial x} + k_y\frac{\partial t}{\partial y} + k_z\frac{\partial t}{\partial z}\right) \tag{2}$$

where

q = heat flux, W/m^2
t = temperature, °C
k_x, k_y, k_z = apparent thermal conductivity in direction of x, y, and z axes, W/(m·K)
grad(t) = gradient of temperature (change in temperature per unit length, perpendicular to isothermal surfaces in solid), K/m
$\partial t/\partial x$ = gradient of temperature along x axis, K/m
$\partial t/\partial y$ = gradient of temperature along y axis, K/m
$\partial t/\partial z$ = gradient of temperature along z axis, K/m

In Equation (2), the thermal conductivity k of the material is assumed to be directionally dependent. In fact, many building materials (e.g., wood and wood-based materials, mineral fiber insulation, perforated bricks) show considerable anisotropy. Therefore, k_x, k_y, and k_z are not equal in these materials; in isotropic materials, they are equal.

Substituting Equation (2) into the relationship for conservation of energy yields

$$\frac{\partial h}{\partial t}\times\frac{\partial t}{\partial \tau} = \mathrm{div}[k\,\mathrm{grad}(t)] + S = \frac{\partial}{\partial x}\left(k_x\frac{\partial t}{\partial x}\right) + \frac{\partial}{\partial y}\left(k_y\frac{\partial t}{\partial y}\right) + \frac{\partial}{\partial z}\left(k_z\frac{\partial t}{\partial z}\right) + S \tag{3}$$

where

h = enthalpy per unit volume, J/m^3
S = heat sources and sinks [e.g., caused by latent heat of evaporation/condensation in presence of moisture, by chemical reactions such as hydration in concrete, or by phase change from solid to liquid or vice versa of special additives consisting of paraffins or salt hydrates, known as phase-change materials (PCM)], W/m^3

with

$$\frac{\partial h}{\partial \tau} = \rho_s c_s + w c_w \tag{4}$$

where

ρ_s = density of solid (dry material), kg/m^3
c_s = specific heat capacity of dry solid, J/(kg·K)
c_w = specific heat capacity of liquid water, J/(kg·K)
w = moisture content, kg/m^3

2.1 STEADY-STATE THERMAL RESPONSE

In steady state without sources or sinks, Equation (3) reduces to

$$\frac{\partial}{\partial x}\left(k_x\frac{\partial t}{\partial x}\right) + \frac{\partial}{\partial y}\left(k_y\frac{\partial t}{\partial y}\right) + \frac{\partial}{\partial z}\left(k_z\frac{\partial t}{\partial z}\right) = 0 \tag{5}$$

If the steady-state heat flux is only in one direction (e.g., perpendicular to the building envelope) and materials are assumed to be isotropic, Equation (2) can be rewritten for each material layer within the building envelope as

$$q = -k_m\frac{\Delta t}{\Delta x} = -C\,\Delta t = -\frac{1}{R}\Delta t \tag{6}$$

where

Δt = temperature difference between two interfaces of one material layer, K
Δx = layer thickness, m
k_m = mean thermal conductivity of material layer with thickness Δx, W/(m·K)
C = thermal conductance of layer with thickness Δx, W/(m^2·K)
R = thermal resistance of layer with thickness Δx, (m^2·K)/W

Licensed for single user. © 2021 ASHRAE, Inc.

Under steady-state conditions, the one-dimensional heat flux is the same through all material layers, but their individual thermal conductance or resistance is usually different.

Surface-to-Surface Thermal Resistance of a Flat Assembly

A single layer's thermal resistance to heat flow is given by the ratio of its thickness to its apparent thermal conductivity. Accordingly, the surface-to-surface thermal resistance of a flat building assembly composed of parallel layers (e.g., a ceiling, floor, or wall), or a slightly curved component, consists of the sum of the resistances of all layers in series:

$$R_s = R_1 + R_2 + R_3 + R_4 + \cdots + R_n \quad (7)$$

where

$R_1, R_2, \ldots, R_n$ = resistances of individual layers, $(m^2 \cdot K)/W$
R_s = resistance of building assembly surface to surface (system resistance), $(m^2 \cdot K)/W$

For building components with nonuniform or irregular sections, such as hollow clay and concrete blocks, use the R-value of the unit as manufactured.

Combined Convective and Radiative Surface Heat Transfer

The surface film resistances and their reciprocal, the surface film coefficients, specify heat transfer to or from a surface by the effects of convection and radiation.

Although heat transfer by convection is affected by surface roughness and temperature difference between air and surface, the largest influence is that of air movement, turbulence, and velocity close to the surface. Because air movement at the envelope's outer surface depends on wind speed and direction, as well as on flow patterns around the building, which are usually unknown, an average surface heat transfer film coefficient at the exterior is normally used. Correlations such as those of Schwarz (1971) link the convective film coefficient to wind speed recorded at a height of 10 m and to orientation of the surface (windward or leeward side). The same holds for the inside surface, where buoyancy plays a prime role. However, because the surface-to-surface thermal resistance of a wall is usually high compared with the surface film resistances, an exact value is of minor importance for most applications.

Because air is rather permeable to long-wave radiation, heat transfer by radiation takes place between the surface of the building and the surfaces of objects in the environment, not the surrounding air. Heat transfer by radiation between two surfaces is controlled by the character of the surfaces (emittance and reflectance), the temperature difference between them, and the angle factor through which they see each other. Indoors, the external wall surface exchanges radiation with partition walls, floor, and ceiling, furniture, and other external walls. In winter, most of the other surfaces have a higher temperature than the external wall surface; therefore, radiative exchange gives a net heat flux to the external wall. Outdoors, the external wall surface sees the ground, neighboring buildings, and the sky. Without sun, thermal radiation from the sky and the environment is normally lower than radiation from the wall. This means the wall is losing energy. Especially during clear nights, the temperature of the exterior wall surface may drop below the ambient air temperature. In this case, convective and radiative heat transfer at the surface are opposed to each other.

For simplicity, convective and radiative surface heat transfer are often combined, leading to an **apparent surface heat transfer film coefficient *h***:

$$q = h(t_{en} - t_s) \quad (8)$$

with

$$h = h_c + h_r \quad (9)$$

where

q = total surface heat transfer, W/m^2
h = apparent surface film transfer coefficient, $W/(m^2 \cdot K)$
h_r = radiant surface film coefficient to account for long-wave radiation exchange, $W/(m^2 \cdot K)$
h_c = convective surface film coefficient, $W/(m^2 \cdot K)$
t_{en} = environmental reference temperature, °C
t_s = surface temperature, °C

For indoor surface heat transfer, this approach is acceptable when only heat transport through the building envelope is considered. Environmental temperature t_{en} also includes the air temperature as the mean temperature of all surfaces in the field of view of the considered envelope assembly. When all these surfaces are of partition walls and floors that have the same temperature as the indoor air, t_{en} may be replaced by the indoor air temperature.

This approach becomes questionable when heat transfer at the outdoor surface is concerned. Because radiation to the sky can lead to surface temperatures below ambient air temperature, Equation (8) underestimates the real heat flux when the environmental temperature is replaced by the outdoor air temperature. Therefore, t_{en} must include all short- and long-wave radiation contributions perpendicular to the assembly's exterior surface. However, t_{en} cannot be used for moisture transfer calculations. Therefore, a more convenient way may be to treat heat transfer by convection and radiation separately. In this case, h_r is skipped in Equation (9), which now applies to convection only, and t_{en} equals the outdoor air temperature. The heat exchange by radiation is calculated by balancing the solar and environmental radiation onto the assembly's exterior surface with the long-wave emission from it.

Steady-state calculation of thermal transport through the building envelope is generally done using surface film resistances based on combined surface heat transfer by radiation and convection, with R being the inverse of the combined surface film coefficient h. Because of greater air movement outdoors, the mean thermal surface film resistance at the exterior surface is lower than at the interior surface. Typical ranges for the combined exterior and interior surface film resistances with surface infrared reflectance ≤0.1 (nonmetallic) are

$$R_o = 0.03 \text{ to } 0.06 \ (m^2 \cdot K)/W$$

$$R_i = 0.12 \text{ to } 0.20 \ (m^2 \cdot K)/W$$

Heat Flow Across an Air Space

Heat flow across an air space is affected by the nature of the boundary surfaces, slope of the air space, distance between boundary surfaces, direction of heat flow, mean temperature of air, and temperature difference between both boundary surfaces. Air space thermal conductance, the reciprocal of the air space thermal resistance, is the sum of a radiation component, a conduction component, and a convection component. For computational purposes, spaces are considered airtight, with neither air leakage nor air washing along the boundary surfaces.

The radiation portion depends on the temperature of the two boundary surfaces and their respective surface properties. Assuming infinite parallel plates, radiation is not affected by thickness or slope of the air space, direction of heat flow, or which surface is hot or cold. For surfaces that can be considered ideally gray, the surface properties are emittance, absorptance, and reflectance. Chapter 4 explains all three in depth. For an opaque surface, reflectance is equal to one minus the emittance, which varies with surface type and condition and radiation wavelength. The combined effect of the emittances of the two boundary surfaces is expressed by the effective emittance E of the air space. Table 2 in Chapter 26 lists typical emittance values for reflective surfaces and building materials, and

Licensed for single user. © 2021 ASHRAE, Inc.

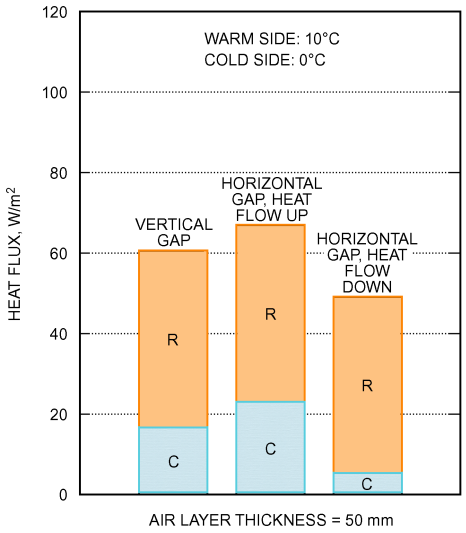

Fig. 5 Heat Flux by Thermal Radiation and Combined Convection and Conduction Across Vertical or Horizontal Air Layer

the corresponding effective emittance for air spaces. More exact surface emittance values should be obtained by tests.

The convective portion is affected markedly by the slope of the air space, direction of heat flow, temperature difference across the space, and, in some cases, thickness of the space. It is also slightly affected by the mean temperatures of both surfaces.

For air spaces in building components, radiation and convection together define total heat flow. An example of their magnitudes for total flow across a vertical or horizontal airspace (up and down) is given in Figure 5.

Table 3 in Chapter 26 lists typical thermal resistance values of sealed air spaces of uniform thickness with moderately smooth, plane, parallel surfaces. These data are based on experimental measurements (Robinson et al. 1954). Resistance values for systems with air spaces can be estimated from these results if emittance values are corrected for field conditions. However, for some common composite building insulation systems involving mass-type insulation with a reflective surface in conjunction with an air space, the resistance value may be appreciably lower than the estimated value, particularly if the air space is not sealed or of uniform thickness (Palfey 1980). For critical applications, a particular design's effectiveness should be confirmed by actual test data undertaken by using the ASTM hot-box method (ASTM *Standard* C1363). This test is especially necessary for constructions combining reflective and nonreflective thermal insulation.

Total Thermal Resistance of a Flat Building Assembly

Total thermal resistance to heat flow through a flat building assembly composed of parallel layers between the environments at both sides is given by

$$R_T = R_i + R_s + R_o \tag{10}$$

where

R_i = combined inner-surface film resistance, $(m^2 \cdot K)/W$
R_o = combined outer-surface film resistance, $(m^2 \cdot K)/W$
R_s = resistance of building assembly surface to surface, including thermal resistances of possible air layers in component (system resistance), $(m^2 \cdot K)/W$

Thermal Transmittance of a Flat Building Assembly

The thermal transmittance or U-factor of a flat building assembly composed of parallel layers is the reciprocal of R_T:

$$U = 1/R_T \tag{11}$$

Calculating thermal transmittance requires knowing the (1) apparent thermal resistance of all homogeneous layers, (2) thermal resistance of the nonhomogeneous layers, (3) surface film resistances at both sides of the construction, and (4) thermal resistances of air spaces in the construction. The lower values of the surface film resistances given previously should be used.

The steady-state heat flux Q_n across the building envelope assembly is then defined by

$$Q_n = A_n U_n (t_i - t_o) \tag{12}$$

where

t_i, t_o = indoor and outdoor reference temperatures, °C
A_n = component area, m^2
U_n = U-factor of component, $W/(m^2 \cdot K)$

Interface Temperatures in a Flat Building Component

The temperature drop through any layer of an assembly is proportional to its thermal resistance. Thus, the temperature drop Δt_j through layer j is

$$\Delta t_j = \frac{R_j (t_i - t_o)}{R_T} \tag{13}$$

The temperature in an interface j then becomes ($t_o < t_i$)

$$t_j = t_o + \frac{R_o^j}{R_T}(t_i - t_o) \tag{14}$$

where R_o^j is the sum of thermal resistances between inside and interface j in the flat assembly, in $(m^2 \cdot K)/W$.

If the apparent thermal conductivity of materials in a building component is highly temperature dependent, the mean temperature must be known before assigning an appropriate thermal resistance. In such a case, apply successive calculation steps; some software can perform these iterative calculations. First, select the thermal resistances for the particular layers. Then calculate total resistance R_T with Equation (9) and the temperature at each interface using Equation (13). The mean temperature in each layer (arithmetic mean of its surface temperatures) can then be used to obtain second-generation R-values. The procedure is repeated until the R-values are correctly selected for the resulting mean temperatures. Generally, this demands two or three steps.

To calculate interior surface temperatures for risk assessment of surface condensation or mold growth, the higher interior and lower exterior surface film resistance values, given previously, should be used.

Series and Parallel Heat Flow Paths

In many building assemblies (e.g., wood-frame construction), components are arranged so that heat flows in parallel paths of different conductances. If no heat flows through lateral paths, the thermal transmittance through each path may be calculated. The average transmittance of the enclosure is then

$$U_{av} = aU_a + bU_b + \cdots + nU_n \tag{15}$$

where $a, b, \ldots, n$ are the surface-weighted path fractions for a typical basic area composed of several different paths with transmittances $U_a, U_b, \ldots, U_n$.

If heat can flow laterally with little resistance in any continuous layer, so that transverse isothermal planes result, the flat construction performs as a series combination of layers, of which one or more provide parallel paths. Total average resistance $R_{T(av)}$ in that case is the sum of the resistance of the layers between the isothermal

Licensed for single user. © 2021 ASHRAE, Inc.

planes, each layer being calculated and the results weighted by the contributing surface area. For further information, see Chapter 27.

The U-factor, assuming parallel heat flow only, is usually lower than that assuming combined series-parallel heat flow. The actual U-factor lies between the two. Without test results, a best choice must be selected. Generally, if the construction contains a layer in which lateral heat conduction is high compared to heat flux through the wall, a value closer to the series-parallel calculation should be used. If, however, there is no layer of high lateral thermal conductance, use a value closer to the parallel calculation. For assemblies with large differences in material thermal conductivities (e.g., assemblies using metal structural elements), the zone method is recommended (see Chapter 27) or the methods discussed in the following section.

Thermal Bridging and Thermal Performance of Multidimensional Construction

Passing highly conductive materials through insulation layers (**thermal bridging**) results in building envelopes with higher overall thermal transmittances and colder surface temperatures compared to an assembly with continuous, unbroken insulation. Not recognizing the effect of thermal bridging on the building envelope's thermal performance can lead to inefficient design of HVAC systems, building operation inefficiencies, inadequate condensation resistance at component intersections, and compromised occupant comfort.

Heat flow through building envelopes occurs in two and three dimensions when considering all components and their intersections (e.g., glazing, wall, roof, parapet, balconies, floor slabs). Multidimensional heat flow caused by highly conductive thermal bridges (e.g., steel and concrete sections) cannot be effectively evaluated using simplified hand calculations (see Chapter 27) and must be evaluated using a multidimensional computer model or guarded hot-box test measurement (ASTM *Standard* C1363).

Construction details are often lumped into an overall heat flow of the entire opaque area or evaluated separately by defining an effective length or area (or zone of influence). Individual details with transmittances defined by an **effective area** are combined with other components to calculate an overall thermal transmittance using a weighted average method. However, effective areas often have no real significance or have a large variance that depends on many factors (location of insulation layers in relation to structural framing, insulation levels, orientation of structural framing, predominate heat flow path, etc.). Moreover, the effect of individual details is averaged over the adjacent assemblies, regardless of size of the effective area or length. Consequently, the absolute effect or thermal quality of a detail is difficult to assess using an effective area approach (Morrison Hershfield 2011).

Contributions of heat flow for specific construction details (e.g., slab edges, parapets, glazing transitions) are best quantified by determining the extra heat loss caused by an individual detail (i.e., thermal bridge at an intersection of components) above the heat loss of the undisturbed assembly and ascribe that difference to a line or point through their linear or point thermal transmittance. This method can simplify calculation of overall heat loss and highlight the effect of the thermal bridge (Morrison Hershfield 2011).

Linear and Point Thermal Transmittances

Using linear and point thermal transmittance requires dividing thermal transmittances into three categories:

- **Clear field**: heat loss if no thermal bridges modified the heat flow through the assembly (area based)
- **Linear**: additional heat loss along a considerable portion of a building perimeter or height in one dimension (e.g., slab edges, balconies, parapets, corner framing, window interfaces)
- **Point**: additional heat loss from thermal bridges at countable points on a building (e.g., three-way corners, beam penetrations)

Calculating the overall heat flow is simply adding the contribution of each linear and point thermal transmittance to the clear-field assembly heat flow. The overall heat flow through the opaque elements of the building envelope (wall or roof) then is

$$Q = \sum Q_{anomalies} + \sum Q_o = \sum (\Psi L) + \sum \chi + \sum Q_o \quad (16)$$

where

Q = overall heat flow through building envelope, W/K
$Q_{anomalies}$ = additional heat flow for linear and point transmittance details, W/K
Q_o = clear-field heat flow without linear and point transmittance details, W/K
Ψ = linear transmittance, W/(m·K)
χ = point transmittance, W/K
L = characteristic length of linear transmittance detail, m

The overall heat flow per unit area, U-value, can be derived by dividing the previous equation by the total projected surface area of the assembly considered.

$$U = \frac{\sum (\Psi L) + \sum \chi}{A_{Total}} + U_o \quad (17)$$

where

U = overall thermal transmittance, including anomalies, W/(m²·K)
U_o = clear field thermal transmittance (assembly), W/(m²·K)
A_{total} = total opaque projected surface area, m²

Thermal bridging and multidimensional heat flow also affect surface temperatures, concealed surfaces, and surfaces exposed to the indoor and outdoor environments. The temperature distribution from multidimensional heat flow is important to consider for controlling localized dirt pick-up on cold surfaces, mold growth, and condensation. A practical, convenient means to evaluate surface temperatures for multidimensional construction is to represent the coldest surface temperatures of interest relative to a temperature difference. This nondimensional ratio is sometimes referred to as a temperature index, factor, or ratio, with the following basic form but represented by many different symbols (CAN/CSA *Standard* A440; ISO *Standard* 13788; Morrison Hershfield 2011):

$$T_{index} = \frac{T_{surface} - T_{outdoor}}{T_{indoor} - T_{outdoor}} \quad (18)$$

where

T_{index} = temperature index
$T_{surface}$ = coldest temperature of surface
$T_{outdoor}$ = outdoor temperature
T_{indoor} = indoor temperature

The temperature index for a critical surface can then be compared to a minimum or design temperature index based on numerous performance criteria (e.g., risk of condensation, mold growth, corrosion). More detailed discussion of using temperature ratios and hygrothermal analysis can be found in the section on Simplified Hygrothermal Design Calculations and Analyses.

2.2 TRANSIENT THERMAL RESPONSE

Steady-state calculations are used to estimate the net heating energy demand on a monthly basis in cold and cool climates. However, in climates where daily temperature swings oscillate around a comfortable mean temperature, transient analysis to define net energy demand for heating and cooling and judge overheating probability is more appropriate. In order of importance, the thermal response of a building to daily swings in temperature and solar

Licensed for single user. © 2021 ASHRAE, Inc.

radiation depends on the thermal transmittance and solar heat gain coefficient (SHGC) of transparent components (fenestration) in the envelope, ventilation strategy, accessible thermal capacity of the internal walls and floors, and thermal transmittance/inertia of opaque components in the envelope.

The effects of the mutual dependences of these four factors are complex. In cool climates, a simplified approach that accounts for these interactions combines a steady-state daily mean heat balance for a most probable hot day with a lower-limit value for the daily harmonic temperature damping at room level. Temperature damping at room level increases with higher admittance and higher harmonic thermal resistance of opaque envelope components; higher admittance and higher harmonic thermal resistance of all inside walls, floor, and ceiling; and higher thermal inertia of furniture and furnishings. A lower thermal transmittance of transparent components in the envelope and more outdoor air ventilation results in decreased daily harmonic temperature damping at room level. In general, however, and in any climate, whole-building simulations complying with ANSI/ASHRAE *Standard* 140 are recommended when a clear picture of overheating probability and net energy demand for heating and cooling is needed.

High admittances presume the presence of thermal storage materials that are easily assessable for heat. Stored heat can be sensible or latent, as shown in Equation (19). The first requires the use of heavy materials with high and constant capacitance and sufficient thickness to store heat by increasing the temperature of the materials (e.g., bricks, stone, sand-lime stone, concrete).The second uses phase change materials (PCMs), which are materials that store heat by changing phase, typically between solid to liquid. Most models used in building energy simulation programs simulate PCMs by using a temperature-dependent specific heat or enthalpy formulation of Equation (19).

$$\rho c V \frac{dT}{dt} = kA \frac{\partial}{\partial x}\left(\frac{\partial T}{\partial x}\right) \tag{19}$$

where

ρ = density, kg/(m^3)
c = specific heat, kJ/(kg·K)
V = volume, m^3
dT/dt = gradient of temperature with respect to time, K/s
k = thermal conductivity, W/(m·K)
A = surface area, m^2
$\partial T/\partial x$ = gradient of temperature along x axis, K/m

There are multiple approaches to solve for transient heat transfer equation. Chapters 4 and 18 describe some approaches to solve for transient problem; Mitchel and Braun (2012) provide more detail. For information about PCM standards and properties, see Chapter 26.

3. AIRFLOW

Airflow through and within building components is driven by stack pressure, wind pressure, and pressure differentials induced by mechanicals. These driving forces are all described in greater detail in Chapters 16 and 24. In calculating air flux in buildings, a distinction must be made between flow through open porous materials, and that through open orifices such as layers composed of small elements, cavities, cracks, leaks, and intentional vents. Air flux through an open porous material is given by

$$m_a = -k_a \,\mathrm{grad}(P_a) \tag{20}$$

where

m_a = air flux, kg/(s·m^2)
k_a = air permeability of open porous material, kg/(Pa·s·m)
grad(P_a) = gradient in total air pressure (stack, wind, and mechanical systems), (Pa/m

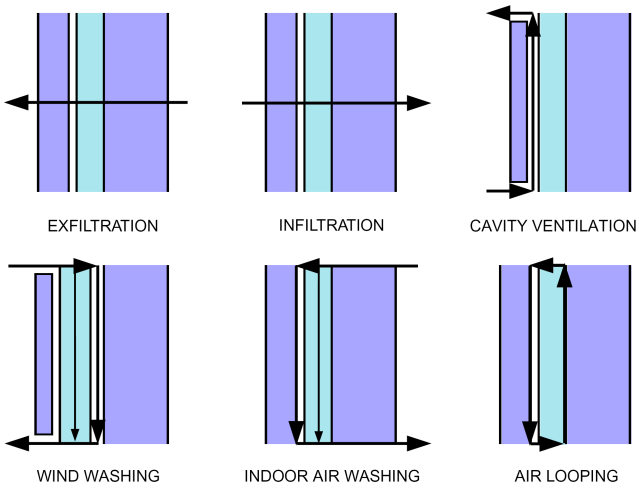

Fig. 6 Examples of Airflow Patterns

The air flux or air transfer equation for flow through the various orifice types is

$$m_a \text{ or } M_a = C(\Delta P_a)^n \tag{21}$$

where the flow coefficient C and flow exponent n are determined experimentally.

As shown in Figure 6, there are six simplified single airflow patterns characteristic of flow in buildings:

- **Exfiltration (air outflow)**: air passes across an envelope component moving from inside the building to the outdoors
- **Infiltration (air inflow)**: air passes across an envelope component from the outdoors to the indoors
- **Cavity ventilation**: outdoor air flows along an air cavity at the exterior of the thermal insulation layer without washing or penetrating the insulation layer
- **Wind washing**: outdoor air permeates the thermal insulation layer and/or flows along the air layer behind
- **Indoor air washing**: indoor air permeates the thermal insulation layer and/or flows along the air layer in front
- **Air looping**: buoyancy forces cause air to flow around and wash the thermal insulation layer filling a cavity

In reality, these single patterns never act in isolation but in combination, creating complicated airflow networks along and through building components. These combined flows act to degrade the hygrothermal response of components, envelopes, and even whole building fabrics. For calculating airflow in such cases, Kronvall (1982) developed an equivalent hydraulic network methodology, which was adapted by Janssens (1998) to calculate airflow in low-mass sloped roofs.

A single layer with low air permeability (an **air barrier**) can substantially minimize air inflow and outflow as long as it is both continuous and leak free. An air barrier must also be strong enough to withstand the air pressure difference imposed across the building envelope. This approach can also avoid moisture damage by preventing airflow through the building envelope.

Heat Flux with Airflow

Air leakage through building components may undesirably contribute to the ventilation in a building beyond that needed for comfort and indoor air quality (see Chapter 16). Air also carries energy that may degrade a building's thermal performance. A conditioned building also requires more energy to maintain internal comfort conditions when conditioned air is able to leak out of the building,

Licensed for single user. © 2021 ASHRAE, Inc.

and unconditioned air is able to leak into the building through infiltration. Airflow changes the assumption implicit in Equation (1), that no mass flow develops in the solid. In general, the sensible heat (enthalpy) displaced by airflow equals

$$\Phi = cM_a(t - t_o) \quad (22)$$

where

c = specific heat capacity of air, kJ/(kg·K)
M_a = airflow, kg/s
t = air temperature, °C
t_o = reference temperature, °C

Only a few simple steady-state cases of combined heat conduction and air-carried enthalpy displacement can be solved analytically. In most cases, testing is the preferred way to get information about the impact. Note that enthalpy flow can increase heat exchange substantially, while reducing temperature damping and time shifting. For example, a full-scale straw bale wall was constructed according to the Tucson, Arizona, structural code with stucco on the exterior side and two layers of 13 mm gypsum board on the interior, with a straw bale thickness of 470 mm. The thermal resistance of the straw by itself was measured as 12.3 (m·K)/W. However, the measured heat flow (in a hot box, tested according to ASTM *Standard* C1363) was more than twice that expected for the level of thermal resistance. Subsequent dissection of the wall revealed small gaps between the facing surfaces and the straw bales, creating air looping, as shown in Figure 6. A computational fluid dynamics model, using the measured anisotropic air permeability of the straw bales, explored the increased heat transfer through the wall caused by circulation through these gaps. That model found that without the gaps, the wall would have performed as predicted, even considering the relatively high air permeance of the straw itself. However, even very small gaps increased the heat transfer to a value comparable to the experimental measurements. A second wall was built with special attention paid to eliminating these gaps, and the heat transfer fell by 60% (Christian et al. 1998).

4. MOISTURE TRANSFER

Moisture may enter a building envelope by various paths, including construction moisture, water leaks, wind-driven rain, rising damp, and foundation leaks. Water vapor activates sorption in the envelope materials, and water vapor flow in and through the envelope may cause condensation on both nonporous and wet, porous surfaces.

Visible and invisible degradation caused by moisture is an important factor limiting the service life of building components. Invisible degradation includes the decrease of thermal resistance of building and insulating materials and the decrease in strength and stiffness of load-bearing materials. Visible degradation includes (1) mold on surfaces, (2) decay of wood-based materials, (3) spalling of masonry and concrete caused by freeze/thaw cycles, (4) hydration of plastic materials, (5) corrosion of metals, (6) damage from expansion of materials (e.g., buckling of wood floors), and (7) decline in appearance. In addition, high moisture levels can lead to odors.

4.1 MOISTURE STORAGE IN BUILDING MATERIALS

Many building materials are porous. The pores provide a large internal surface, which generally has an affinity for water molecules. In some materials, such as wood, moisture may also be adsorbed in the cell wall itself. The amount of water in these **hygroscopic** (water-attracting) materials is related to the relative humidity of the surrounding air. When relative humidity rises, hygroscopic materials gain moisture (**adsorption**), and when relative humidity drops, they lose moisture (**desorption**). The relationship between relative humidity and moisture content at a particular temperature is represented in a graph called the **sorption isotherm** (Figure 7). Isotherms obtained by adsorption are not identical to those obtained by desorption; this difference is called **hysteresis**. At high relative humidity, small pores become entirely filled with water by capillary condensation. The maximum moisture content should be reached at 100% rh, when all pores are filled, but experimentally this can only be achieved in a vacuum, by boiling the material, or by keeping it in contact with water for an extremely long time. In practice, the maximum moisture content of a porous material is lower. That value is referred to as **free water saturation** w_f or sometimes **capillary moisture content**. Figure 7 shows a typical sorption curve, giving the equilibrium moisture content as a function of relative humidity. The equilibrium moisture content increases with relative humidity, especially above 80% rh. It decreases slightly with increasing temperature. Moisture contents above w_{95} (the equilibrium water content at 95% rh) cannot be

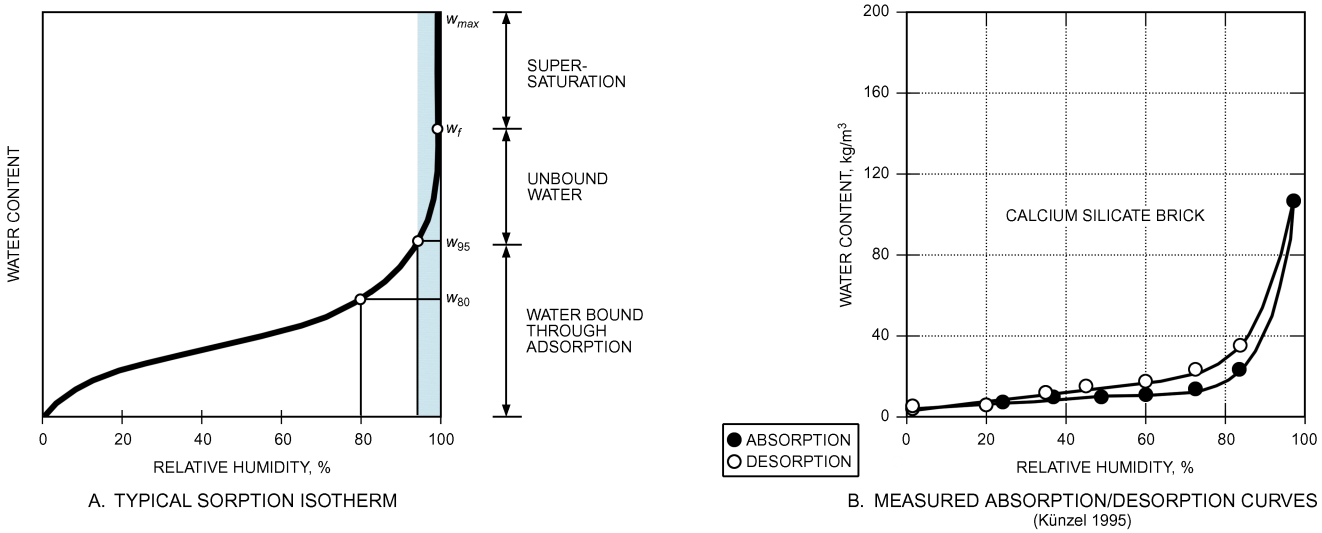

Fig. 7 Sorption Isotherms for Porous Building Materials

(Künzel and Holm 2001)

Licensed for single user. © 2021 ASHRAE, Inc.

achieved solely by vapor adsorption, because this region is characterized by capillary (unbound) water.

Chapter 32 describes hygroscopic substances and their use as dehumidifying agents. Chapter 26 has data on the moisture content of various materials in equilibrium with the atmosphere at various relative humidities. Wood and many other hygroscopic materials change dimensions with variations in moisture content.

Porous materials also absorb liquid water when in contact with it. Liquid water may be present because of construction moisture, leaks, rain penetration, flooding, or surface and interstitial condensation. Wetting may be so complete that the material reaches free water saturation once the largest pores are filled with water. Up to this point there is still a distinct equilibrium between the moisture content of the material and its environment. This becomes evident when different porous materials are brought in direct (capillary) contact with each other. In that case, there is capillary flow from one material to the other until all pores at a certain size are filled with water in both materials; all pores with sizes above this limit remain empty because smaller capillaries have a higher suction force than larger ones. This phenomenon is used to determine the moisture storage function above 95% rh, which represents the limit of vapor sorption tests in climatic chambers. Dalehaug et al. (2005), Krus (1996), and Roels et al. (2003) described using a pressure plate apparatus, in which water-saturated material samples are placed on a porous membrane permeable to water but impermeable to air. Then pressure is applied in different steps until capillary equilibrium is achieved. The equilibrium moisture content at each pressure step is determined by weighing the samples. The moisture storage function from zero pressure (free water saturation at 100% rh) up to 10 MPa, which corresponds to approximately 93% rh, is defined by plotting the equilibrium water content over the applied pressure (Figure 8), which is assumed to be equal to the suction pressure of the largest still-water-filled capillaries.

For a continuous moisture storage function from the dry state to 100% rh, the sorption isotherm and the resultant curve from the pressure plate test are combined, either by converting the suction pressure into relative humidity or vice versa, using Kelvin's equation:

$$\phi = \exp\left(-\frac{s}{\rho_w R_D T}\right) \tag{23}$$

where

ϕ = relative humidity of air in pores
s = suction pressure, Pa
ρ_w = density of water, kg/m^3
R_D = gas constant for water vapor, J/(kg·K)
T = absolute temperature, K

The hatched zones in Figure 8 represent the overhygroscopic range where the converted results from pressure plate tests are plotted to complete the sorption isotherm. This narrow range is less important if vapor diffusion is the dominant moisture transport mechanism, for which an approximative interpolation of the moisture storage function between the end of the sorption isotherm and the free water saturation suffices. However, if capillary water flow from one material to the other becomes dominant (e.g., water absorption by bricks from mortar or stucco), the influence of the pressure plate results on the calculation's outcome may not be negligible (Krus 1996). In that case, the detailed suction curve (Figure 8, right) should be used for simulations.

4.2 MOISTURE FLOW MECHANISMS

Water vapor and liquid water migrate by a variety of transport mechanisms, including the following:

- Water vapor diffusion by partial water vapor pressure gradients
- Displacement of water vapor by air movement
- Surface diffusion and capillary suction of liquid water in porous building materials
- Liquid flow by gravity or water and air pressure gradients

In the past, moisture control strategies focused on water vapor diffusion. Displacement of water vapor by air movement was treated superficially, and liquid water transport provoked by wind-driven rain or soil moisture was overlooked almost completely. When present, however, these mechanisms can move far greater amounts of moisture than diffusion does. Therefore, air movement and liquid flow have a high priority in moisture control.

Liquid flow by gravity and by pressure gradients is not discussed here, but a short description of the other mechanisms follows. More comprehensive treatment of moisture transport and storage may be found in Hens (1996), Künzel (1995), and Pedersen (1990). For a discussion of water vapor in air, see Chapter 1.

Water Vapor Flow by Diffusion

Normally, diffusion moves water vapor through air and building materials, in small quantities. As a driver, it can still be important in industrial applications, such as cold-storage facilities and built-in refrigerators, or in buildings where a high indoor partial water vapor pressure is needed or present because of activities in the space (e.g., in natatoriums). Controlling diffusion also becomes more important with increasingly airtight construction.

The equation used to calculate water vapor flux by diffusion through materials is based on Fick's law for diffusion of a very dilute gas (water vapor) in a binary system (water vapor and dry air):

$$m_v = -\mu_p \, \mathrm{grad}(p) \tag{24}$$

where

$\mathrm{grad}(p)$ = gradient of partial water vapor pressure, Pa
μ_p = water vapor permeability of porous material, kg/(Pa·s·m)

According to Equation (24), water vapor flux by diffusion closely parallels Fourier's equation for heat flux by conduction. However, actual diffusion of water vapor through a material is far more complex than the equation suggests. For hygroscopic materials, water vapor permeability may be a function of relative humidity or, more accurately, moisture content. Also, temperature has an impact. The permeability may even vary spatially or by orientation because of variations or anisotropy in the material's porous system.

Test methods for measuring water vapor permeability are described in ASTM *Standard* E96. Water vapor flux through a material is determined gravimetrically while maintaining constant temperature and partial water vapor pressure differential across the specimen. Tests are usually done in a climatic chamber at controlled temperature (20 or 23°C) and 50% rh. The material samples are sealed to the top of a cup that contains either a desiccant (dry-cup) or water or a saturated salt solution (wet-cup).

Permeability is usually expressed in kg/(Pa·s·m) and permeance in kg/(Pa·s·m^2). Whereas *permeability* refers to the water vapor flux per unit thickness, *permeance* is used in reference to a material of a specific thickness. For example, a material that is 50 mm thick generally is assumed to have half the permeance of a 25 mm thick material, even though permeances of many materials often are not strictly proportional to thickness. In many cases, the property ignores the effect of cracks or holes in the surface. It is inappropriate to refer to permeability with regard to inhomogeneous or composite materials, such as structural insulated panels (SIPs) or film-faced insulation batts.

Methods have been developed that allow measurement of water vapor transport with temperature gradients across the specimen (Douglas et al. 1992; Galbraith et al. 1998; Krus 1996). These methods may give more accurate data on water vapor transfer through materials and eventually allow better distinction between the various transport modes.

There are some plastic materials [e.g., polyamide (Künzel 1999)] where the vapor permeability rises substantially with ambient relative humidity because of slight changes in the pore structure: water molecules squeeze between polymer molecules and thereby create new passages through the material. This effect is called **solution diffusion**. Moisture transport by solution diffusion can be described by Equation (23) using humidity-dependent vapor permeability functions determined by cup tests at several average relative humidity steps.

Water Vapor Flow by Air Movement

Air transports not only enthalpy but also the water vapor it contains. Related water vapor flux is represented by

$$m_v = W m_a \approx \frac{0.62}{P_a} \, m_a p \tag{25}$$

where

W = humidity ratio of moving air
m_a = air flux, kg/(s·m^2)
p = partial water vapor pressure in air, Pa
P_a = atmospheric air pressure, Pa

Even small air fluxes can carry much larger volumes of water vapor compared to vapor diffusion. However, potentially damaging airflow mostly occurs through cracks and leaky joints rather than through the entire area of a building component. Exceptions include masonry, tiled roofs, slated roofs, mineral and glass wool boards, wood wool, and cement boards.

Water Flow by Capillary Suction

Within small pores of an equivalent diameter less than 0.1 mm, molecular attraction between the pore wall and the water molecules causes capillary suction (Figure 9), defined as

$$s = \frac{2\sigma \cos\theta}{r} \tag{26}$$

where

s = capillary suction, Pa
σ = surface tension of water, N/m
r = equivalent radius of capillary, m
θ = contact wetting angle, degrees

The contact angle is the angle between the water meniscus and capillary surface. The smaller the contact angle, the larger the capillary suction. In hydrophilic (water-attracting) materials, the contact wetting angle is less than 90°; in hydrophobic (water-repelling) materials, it is between 90 and 180°.

Capillary water movement is governed by the gradient in capillary suction s:

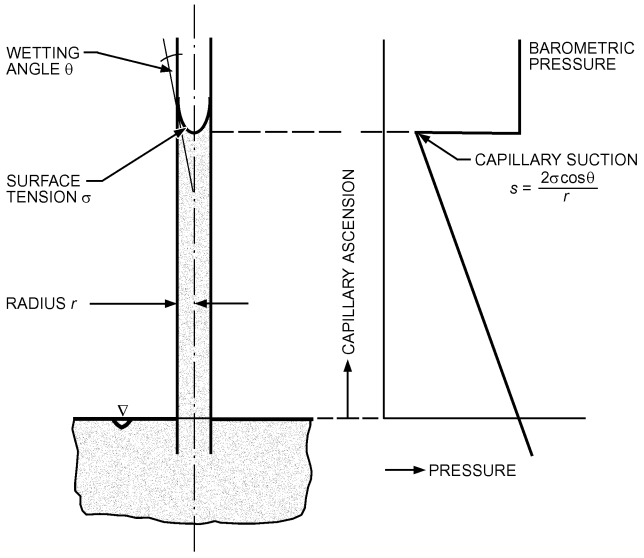

Fig. 9 Capillary Rise in Hydrophilic Materials

Licensed for single user. © 2021 ASHRAE, Inc.

$$m_l = -k_m \, \text{grad}(s) \quad (27)$$

where

m_l = liquid flux, kg/(s·m²)
k_m = water permeability, kg/(Pa·s·m)

Alternatively, with relative humidity as the driving factor [for the conversion, see Kelvin's Equation (23)]:

$$m_l = -\delta_\phi \, \text{grad}(\phi) \quad (28)$$

where δ_ϕ is the liquid transport coefficient related to the relative humidity as driving potential, in kg/(m·s).

Capillary suction is greater in smaller capillaries, so water moves from larger to smaller capillaries. In pores with constant equivalent radius, water moves toward zones with smaller contact angles. Although surface tension is a decreasing function of temperature (the higher the temperature, the lower the surface tension) and water moves toward zones with lower temperature, that effect is small compared to the effect of equivalent pore diameter and contact angle.

Capillary suction increases linearly with the inverse of the radius [see Equation (26)], but the flow resistance increases proportionally to the fourth power of the inverse radius. Therefore, larger pores have a much greater liquid transport capacity than smaller pores. Because larger pores can only be filled with water once the smaller pores are saturated, the liquid transport capacity is a function of moisture content. Thus, water permeability k_m and liquid transport coefficient δ_ϕ are also functions of water content. Determination of these functions is, however, quite difficult because it requires the measurement of suction with respect to relative humidity distributions during transient water absorption and drying tests (Plagge et al. 2007).

Whereas measuring suction requires experience and special preparation of material samples, determining one-dimensional moisture content distributions in porous building materials can be done accurately with state-of-the-art scanning technologies using nuclear magnetic resonance (NMR), or gamma ray or x-ray attenuation (Krus 1996; Kumaran 1991; van Besien et al. 2002). Transient water content profiles recorded during such scanning tests serve to determine the liquid diffusivity D_w of the examined material, which is defined by

$$m_l = -D_w \, \text{grad}(w) \quad (29)$$

where

w = moisture content, kg/m³
D_w = liquid diffusivity, m²/s

For most hygroscopic building materials, D_w is a function of moisture content.

Although Equation (29), which resembles Fick's law for diffusion, would seem a natural choice for calculating liquid flow, its use is not recommended because water content is not a continuous potential in building envelopes consisting of different materials. Using Equation (27) or (28) is recommended because relative humidity ϕ and capillary suction s are considered to be continuous potentials (no jumps at material interfaces). Where diffusivity functions are available, the liquid transport coefficient δ_ϕ in Equation (28) can be determined by

$$\delta_\phi = D_w \, dw/d\phi \quad (30)$$

where $dw/d\phi$ is the slope of the moisture retention curve, in kg/m³.

Liquid Flow at Low Moisture Content

The explanation of liquid flow at low moisture content is still a matter of controversy. Some researchers assume it is surface diffusion (e.g., Krus 1996), whereas others believe liquid flow only fully starts beyond critical moisture content (Carmeliet et al. 1999; Kumaran et al. 2003; Vos and Coelman 1967). Liquid flow begins within the hygroscopic range, and is often mistaken for a part of vapor diffusion. In porous materials with a fixed pore structure, the apparent increase in vapor permeability during a wet-cup test may be partly because of liquid transport phenomena, and partly to shorter diffusion paths among water islands in the porous system formed by capillary condensation. Surface diffusion is defined as molecular movement of water adsorbed at the pore walls of the material. The driving potential is the mobility of the molecules, which depends on relative humidity in the pores (i.e., the adsorbed water migrates from zones of high to low relative humidity). Liquid flow, if present at low moisture content, can be described by Equations (28) or (29), as for capillary flow.

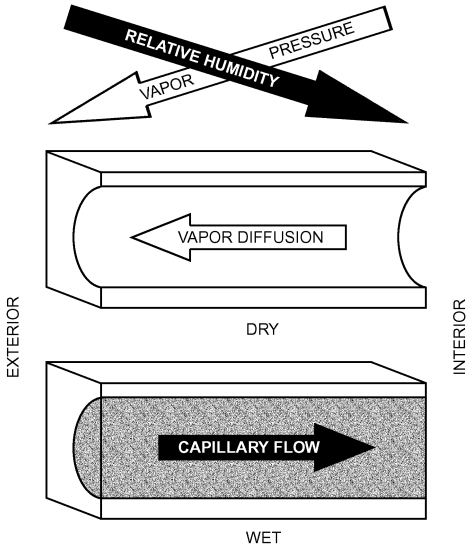

Fig. 10 Moisture Fluxes by Vapor Diffusion and Liquid Flow in Single Capillary of Exterior Wall under Winter Conditions

Under isothermal conditions, it is impossible to differentiate between vapor and liquid flow at low moisture content. However, in the presence of a temperature gradient, both transport processes may oppose each other in a pore; the fluxes may go in opposite directions (Künzel 1995). This can be explained by looking at the physical processes in a single capillary going through a wall, as shown in Figure 10. For heating climates in winter, the indoor vapor pressure is usually higher than outdoors while the indoor humidity is lower than outdoors. Therefore, the partial vapor pressure gradient is opposed to the relative humidity gradient over the cross section of a exterior wall. Looking at one capillary in that wall under very dry conditions (Figure 10), the only moisture transport mechanism is vapor diffusion and the total flux is directed towards the exterior. If the average humidity in the wall rises to 50 to 80% rh, liquid water begins to move in the opposite direction either by surface diffusion or by capillary suction in the nanopores. Under these conditions, the total moisture flux may go to zero if both fluxes are of the same magnitude (Krus 1996). When conditions are very wet (e.g., from wind-driven rain), most of the capillary pores are filled with water, and the dominant transport mechanism is flow by capillary suction.

Transient Moisture Flow

It is difficult to experimentally distinguish between liquid flow by suction and water vapor flow by diffusion in porous, hygroscopic materials. Because these materials have a very complex porous system and each surface is transversed by liquid-filled pore fractions and vapor-filled pore fractions, vapor and liquid flow are often treated as parallel processes. This allows expression of moisture flow as the summation of the two transport equations, one using

Licensed for single user. © 2021 ASHRAE, Inc.

water vapor pressure to drive water vapor flow by diffusion, and the other using either capillary suction or relative humidity ϕ to drive liquid moisture flow. The conservation equation in that case can be written as

$$\frac{\partial w}{\partial t} = -\,\mathrm{div}(m_w + m_v) + S_w \tag{31}$$

where

w = moisture content of building material, kg/m^3
m_v = water vapor flux, kg/(m^2·s)
m_w = liquid water flux, kg/(m^2·s)
S_w = moisture source or sink, kg/(m^3·s)
div = divergence (resulting inflow or outflow per unit volume of solid), m^{-1}

Vapor and liquid fluxes are given by Equations (23), (27), and (28), which may be rewritten in terms of only two driving forces capillary suction pressure s and partial vapor pressure p:

$$\frac{\partial w}{\partial s} \times \frac{\partial s}{\partial t} = \mathrm{div}\left[k_m \mathrm{grad}(s) + \mu_p \mathrm{grad}(p)\right] + S_w \tag{32}$$

where

s = capillary suction pressure, Pa
p = partial vapor pressure, Pa
μ_p = vapor permeability (related to partial vapor pressure), kg/(Pa·s·m)
k_m = water permeability (related to partial suction pressure), kg/(Pa·s·m)
S_w = moisture source or sink, kg/(m^3·s)

Alternatively, suction pressure s in Equation (32) can be replaced by relative humidity as the sole variable, with saturation pressure p_{sat} only a function of temperature:

$$\frac{\partial w}{\partial \phi} \times \frac{\partial \phi}{\partial \tau} = \mathrm{div}\left[\delta_\phi \mathrm{grad}(\phi) + \mu_p \mathrm{grad}(\phi p_{sat})\right] + S_w \tag{33}$$

where

ϕ = relative humidity, %
p_{sat} = saturation vapor pressure, Pa
μ_p = vapor permeability (related to partial vapor pressure), kg/(Pa·s·m)
δ_ϕ = liquid transport coefficient (related to relative humidity), kg/(s·m)

Because of the strong temperature dependence of vapor pressure with respect to saturation vapor pressure, Equation (32) with respect to (33) must be coupled with Equation (3) to describe nonisothermal moisture flow. Under isothermal conditions, Equation (32) with respect to (33) could be solved independently. However, pure isothermal conditions hardly ever exist in reality; as soon as water evaporates or condenses, the latent heat effect leads to temperature differences. Other potentials may be used if material properties appropriate to those potentials are available.

5. COMBINED HEAT, AIR, AND MOISTURE TRANSFER

Combined heat, air, and moisture transfer can have a detrimental effect on a building. Air in- and exfiltration short-circuit the U-factor as a designed wall performance. Wind washing, indoor air washing, and stack-induced air movement may increment the U-factor by a factor of 2.5 or more. High moisture levels in building materials may also have a negative effect on the building envelope's thermal performance. Therefore, it is advisable to analyze the combined heat, air, and moisture transfer through building assemblies. However, some of these transport phenomena, especially those involving airflow, are three-dimensional in nature and difficult to predict because they mostly occur through accidental gaps, cracks, or imperfect joints. Research into these effects is ongoing, but at present, practitioners can only use simplified tools or hygrothermal models that do not yet cover all airflow-, gravity-, and pressure-gradient-induced moisture flow aspects.

6. SIMPLIFIED HYGROTHERMAL DESIGN CALCULATIONS AND ANALYSES

6.1 SURFACE HUMIDITY AND CONDENSATION

Surface condensation occurs when water vapor contacts a nonporous surface that has a temperature lower than the dew point of the surrounding air. Insulation should therefore be thick enough to ensure that the surface temperature on the warm side of an insulated assembly always exceeds the dew-point temperature there. However, even without reaching the dew point, relative humidity at the surface may become so high that, given enough time, mold growth occurs. According to Hens (1990), a simple design rule is that surface relative humidity in layers warmer than 5°C should not exceed 80% on a monthly mean basis.

The temperature ratio f_{h_i} is useful for calculating the surface temperature:

$$f_{h_i} = \frac{t_s - t_o}{t_i - t_o} \tag{34}$$

where

t_s = surface temperature on warm side, °C
t_o = ambient temperature on cold side, °C
t_i = ambient temperature on warm side, °C

The minimum temperature ratio to avoid surface condensation is

$$f_{h_i,min} = \frac{t_{d,i} - t_o}{t_i - t_o} \tag{35}$$

where $t_{d,i}$ is the dew point of ambient air on the warm side, °C.

The minimum insulation thickness to avoid surface condensation on a flat element can be calculated from

$$L_{min} = k\left[\frac{f_{h_i,min}}{h_i(1 - f_{h_i,min})} - R_{add}\right] \tag{36}$$

where R_{add} is the thermal resistance between the surface on the warm side and the cold ambient for the wall without thermal insulation, (m^2·K)/W.

The condensation resistance of glazing is often estimated from outdoor and indoor design temperatures, U-factor of the window assembly, and air film resistance. A window assembly may have different U-factors at the glass, frame, and edge where the glass meets the frame; condensation resistance must be calculated at each of these locations. A procedure for these calculations can be found in NFRC (2004). The likelihood of window condensation depends strongly on the indoor air film resistance. This resistance may be reduced by washing the window with supply air. It may be increased by using window treatments indoors such as blinds or curtains, or by attaching self-adhesive infrared (IR) reflective films. Condensation on glazing is not inherently damaging, unless water is allowed to run onto painted or other surfaces that can be damaged by water.

6.2 INTERSTITIAL CONDENSATION AND DRYING

Dew-Point Method

The best-known simple steady-state design tools for evaluating interstitial condensation and drying within exterior envelopes (walls, roofs, and ceilings) are the dew-point method and the Glaser method

Licensed for single user. © 2021 ASHRAE, Inc.

(which uses the same underlying principles as the dew-point method, but uses graphic rather than computational methods). These methods assume that steady-state conduction governs heat flow and steady-state diffusion governs water vapor flow. Both analyses compare partial water vapor pressures in the envelope, as calculated by steady-state water vapor diffusion, with saturation water vapor pressures, which are based on calculated steady-state temperatures in the envelope.

The condition where the calculated partial water vapor pressure is greater than saturation has been called **condensation**. Strictly speaking, condensation is the change in phase from vapor to liquid, as occurs on glass, metal, synthetic foils, etc. For porous and hygroscopic building materials (e.g., wood, gypsum, masonry materials), vapor may be adsorbed or absorbed and only forms the droplets usually associated with true condensation when the moisture content passes capillary saturation. Nevertheless, the term *condensation* is used for this method to indicate vapor pressure in excess of saturation vapor pressure, although this could be misleading about actual water conditions on porous and hygroscopic surfaces. This is one of the unfortunate simplifications inherent in a steady-state analytic tool.

Steady-state heat conduction and vapor diffusion impose severe limitations on applicability and interpretation. The greatest one is that the main focus is on preventing sustained interstitial condensation, as indicated by vapor pressures beyond saturation vapor pressures. Many building failures (e.g., mold, buckling of siding, paint failure) are not necessarily related to interstitial condensation; conversely, limited interstitial condensation can often be tolerated, depending on the materials involved, temperature conditions, and speed at which the material dries out. (Drying can only be approximated because both the dew-point and Glaser methods neglect moisture storage and capillary flow.)

Because all moisture transfer mechanisms except water vapor diffusion are excluded, results should be considered as approximations and should be used with extreme care. Their validity and usefulness depend on judicious selection of boundary conditions, initial conditions, and material properties. Specifically, the methods should be used to estimate monthly or seasonal mean conditions only, rather than daily or weekly means. Furthermore, water vapor permeances may vary with relative humidity, and rain, flashing imperfections, leaky or poorly formed joints, rain exposure, airflow, and sunshine can have overriding effects. The dew-point and Glaser methods, however, are still used by design professionals and actually form the basis for most codes dealing with moisture control and vapor retarders.

For those who want to use this simple tool despite its shortcomings, a description of the dew-point method is presented in this chapter, with two application examples in Chapter 27. A comprehensive description of the dew-point and Glaser methods can be found in TenWolde (1994). The dew-point method uses the equations for steady-state heat conduction and diffusion in a flat component, with the vapor flux in a layer written as

$$-m_v = \mu_p \frac{\Delta p}{d} = \frac{\Delta p}{Z} \tag{37}$$

where

m_v = water vapor flux through layer of material, ng/(s·m^2)
Δp = partial water vapor pressure difference across layer, Pa
μ_p = water vapor permeability of material, ng/(Pa·s·m)
d = thickness of layer, m
Z = water vapor resistance, (Pa·s·m^2)/ng

Over time, the dew-point method has been upgraded: (1) the concept of critical moisture content allows accounting for moisture build-up and upgraded calculation of drying, and (2) carried vapor flow has been included, underlining the importance of airtightness to avoid moisture deposition by condensation in building assemblies. Calculations have also been based on monthly mean outdoor weather data, corrected for solar gains, long-wave losses, the nonlinear relation between temperature and water vapor saturation pressure, and monthly mean indoor environmental data rather than on daily extremes (Hens 2007, 2016; Vos and Coelman 1967).

7. TRANSIENT COMPUTATIONAL ANALYSIS

Computer models can analyze and predict the heat, air, and moisture response of building components. These transient models can predict the varying hygrothermal situations in building components for different design configurations under various conditions and climates, and their capabilities are continually improved. Hens (1996) reviewed the state of the art of heat, air, and moisture transport modeling for buildings and identified 37 different models, most of which were research tools that are not readily available and may have been too complex for use by practitioners. Some, however, were available either commercially, free of charge, or through a consultant. Trechsel (2001) provided an update on existing tools and approaches.

For many applications and for design guide development, the actual behavior of an assembly under transient climatic conditions must be simulated, to account for short-term processes such as driving rain absorption, summer condensation, and phase changes. Understanding the application limits of such models is an important part of that process.

The features of a complete moisture analysis model include transient heat, air, and moisture transport formulation, incorporating the physics of contact conditions between layers and materials. Interfaces may be bridgeable for vapor diffusion, airflow, and gravity or pressure liquid flow only. They may be ideally capillary (no flow resistance from one layer to the next) or behave as a real contact (have an additional capillary resistance at the interface).

Not all these features are required for every analysis, though additional features may be needed in some applications (e.g., moisture flow through unintentional cracks and intentional openings, rain penetration through veneer walls and exterior cladding). To model these phenomena accurately, experiments may be needed to define subsystem performance under various loads (Straube and Burnett 1997). It is usually preferable to take performance measurements of system and subsystems in field situations, because only then are all exterior loads and influences captured.

Transient models enable timestep-by-timestep analysis of heat, air, and moisture conditions in building components, and give much more realistic results than steady-state conduction/diffusion and conduction/diffusion/airflow models. However, they are complex and usually not transparent, and require judgment and expertise on the part of the user. Existing models are one, two, or three dimensional, requiring the user to devise a realistic representation of the building component to be analyzed. Users should be aware which transport phenomena and types of boundary conditions are included and which are not. For instance, some models cannot handle air transport or rain wetting of the exterior. Results also tend to be very sensitive to the choice of indoor and outdoor conditions. Usually, exact conditions are not known. Indoor and outdoor conditions to be used were established by ASHRAE *Standard* 160. More extensive data on material properties are available [e.g., Kumaran (2006)], but it can be problematic finding accurate data for all the materials in a component.

Validation, verification, and benchmarking of combined heat, air, and moisture models is a formidable task. Currently, only limited internationally accepted experimental data exist. The main difficulty lies in the fact that it is difficult to measure air and moisture fluxes and moisture transport potentials, even under laboratory conditions. In addition, even an already validated model should be verified for each new application.

Licensed for single user. © 2021 ASHRAE, Inc.

In most full hygrothermal models, common outputs are vapor pressure; temperature; moisture content; relative humidity; and air, heat, and moisture fluxes. Results must be checked for consistency, accuracy, grid independence, and sensitivity to parameter changes. The results may be used to evaluate the moisture tolerance of an envelope system subjected to various interior and exterior loads. Heat fluxes may be used to determine thermal performance under the influence of moisture and airflow. Furthermore, the transient output data may be used for durability and indoor air quality assessment. Postprocessing tools concerning durability (e.g., corrosion, mold growth, freeze and thaw, hygrothermal stress and strain, indoor air humidity) have been developed or are under development. For instance, Carmeliet (1992) linked full hygrothermal modeling to probability-based fracture mechanics to predict the risk of crack development and growth in an exterior insulation finish system (EIFS) by weathering. A transient model to estimate the rate of mold growth was developed by Sedlbauer (2001).

Combined heat, air, and moisture models also have limitations. Rain absorption, for example, can be modeled, but rainwater runoff and its consequences at joints, sills, and parapets cannot, although runoff followed by gravity-induced local penetration is one of the main causes of severe moisture problems. Even an apparently simple problem, such as predicting rain leakage through a brick veneer, is beyond many tools' capabilities. In such cases, simple qualitative schemes and field tests still are the way to proceed (Hens 2007).

7.1 CRITERIA TO EVALUATE HYGROTHERMAL SIMULATION RESULTS

At the building assembly and whole-building level, combined heat, air, and moisture transfer has consequences for thermal comfort, perceived indoor air quality, health, durability, and energy efficiency. Hygrothermal conditions in a building or within a building envelope assembly can be crucial for overall performance of the construction and its mechanical systems. Therefore, simulation results should be compared to limit conditions and widely accepted performance criteria determined for the following performance issues.

Thermal Comfort

Thermal comfort, defined as a condition of mind that expresses satisfaction with the thermal environment (ASHRAE *Standard* 55), depends on two human parameters (clothing and metabolism) and a set of environmental variables, among them relative humidity. At effective temperatures below 25°C, relative humidity's effect on thermal comfort is minimal, but above 25°C, its importance increases as latent heat loss becomes a main mechanism in getting rid of metabolic heat. If, at those temperatures, the air feels too moist, the thermal environment is perceived as uncomfortable. At low relative humidity, polluted air can irritate the mucosa, and electric discharges when touching insulators (e.g., plastic chairs) are felt. However, in most residential buildings and in many offices, temperature is controlled but not relative humidity, except in hot and humid climates. Its instantaneous value depends on the equilibrium between vapor release indoors, ventilation, airflow among rooms, and temporary vapor storage by finishes and furnishings (often called moisture buffering). The average value over longer periods depends on ventilation and vapor release only, influenced somewhat by moisture buffering.

Perceived Air Quality

Air quality may be defined exactly by measuring the pollutants present. However, occupants typically perceive drier, cooler air as smelling "fresher" than humid, warmer air. Thus, temperature and relative humidity affect perception of air freshness. Together, they define the air's enthalpy. Testing shows that higher enthalpy lowers the perception of freshness (Fang et al. 1998). Despite this fact, in most buildings, relative humidity is uncontrolled.

Human Health

Mold in buildings is of concern to occupants. Mold can grow on most surfaces if the relative humidity at the surface is above a critical value, the surface temperature is conducive to growth, and the substrate provides nutritional value to the organism. The growth rate depends on the magnitude and duration of surface relative humidity. Surface relative humidity is a complex function of material moisture content, local surface temperature, and humidity conditions in the space. In recognition of the issue's complexity, the International Energy Agency established a surface relative humidity criterion for design purposes: monthly average values should remain below 80% (Hens 1990). Other proposals include the Canada Mortgage and Housing Corporation's stringent requirement of always keeping surface relative humidity below 65% (CMHC 1999). Although there still is no agreement on which criterion is most appropriate, mold growth can usually be avoided by allowing surface relative humidity over 80% only for short time periods. The relative humidity criterion may be relaxed for nonporous surfaces that are regularly cleaned. Most molds only grow at temperatures above 5°C. Moisture accumulation below 5°C may not cause mold growth if the material is allowed to dry out below the hygroscopic moisture content for a relative humidity of 80% before the temperature rises above 5°C. Mathematical models for predicting a mold growth index were developed by Hukka and Viitanen (1999) and Sedlbauer (2001); these can be linked to results from hygrothermal analysis.

Dust mites trigger allergies and asthma. Dust mites thrive at high relative humidities (over 70%) at room temperature, but will not survive sustained relative humidities below 50% (Burge et al. 1994). Note that these values relate to local conditions in the places that mites tend to inhabit (e.g., mattresses, carpets, soft furniture).

Durability of Finishes and Structure

Moisture behind paint films may cause paint failure, and water or condensation may also cause streaking or staining. Excessive changes in moisture content of wood-based panels or boards may cause buckling or warp. Excessive moisture in masonry and concrete may cause salt efflorescence, or, when combined with low temperatures, freeze/thaw damage and spalling (chipping).

Structural failures caused by wood decay are rare but have occurred (Merrill and TenWolde 1989). Decay generally requires wood moisture content at fiber saturation (usually about 30% by mass) or higher and temperatures between 10 and 40°C. Such high wood moisture contents are possible in green lumber or by absorption of liquid water from condensation, leaks, groundwater, or saturated materials in contact with the wood. To maintain a safety margin, 20% moisture content by mass is sometimes used as the maximum allowable. Because wood moisture content can vary widely with sample location, a local moisture content of 20% or higher may indicate fiber saturation elsewhere. Once established, decay fungi produce water that enables them to maintain moisture conditions conducive to their growth.

Rusting of nails, nail plates, or other metal building components is also a potential cause of structural failure. Corrosion may occur at relative humidities near the metal surface above 60% or as a result of liquid water from elsewhere. Wood moisture content over 20% encourages corrosion of steel fasteners in the wood, especially if the wood is treated with preservatives. In buildings, metal fasteners are often the coldest surfaces, encouraging condensation and corrosion.

Energy Efficiency

Moisture can significantly degrade thermal performance of most insulation materials. Moisture contributes to heat transfer in both

Licensed for single user. © 2021 ASHRAE, Inc.

sensible and latent forms, as well as through mass transfer. The effect depends on the type of insulation material, moisture content, temperature of the insulation material and its thermal history, location of moisture in the insulation material, and the building envelope's interior and exterior environments. Reported relationships between thermal performance of the insulation material and moisture content vary significantly. Kyle and Desjarlais (1994) estimated that water distribution accounts for a difference of up to 25% in heat flux in some cases. Evaporation on the warm side and condensation or adsorption on the cold side add important latent heat components to the heat flux (Kumaran 1987).

Under conditions where water vapor pressure gradients change slowly or where the insulation layer has an extremely low water vapor permeance, little water vapor is transported, but moisture still affects sensible heat transfer in the building envelope component. Epstein and Putnam (1977) and Larsson et al. (1977) showed a nearly linear increase in sensible heat transfer of approximately 3 to 5% for each volume percent increase in moisture content in cellular plastic insulations. For example, an insulation material with about a 5% moisture content by volume has 15 to 25% greater heat transfer than when dry. Other field studies by Dechow and Epstein (1978) and Ovstaas et al. (1983) showed similar results for insulations installed in below-grade applications such as foundation walls.

THIS chapter contains material property data related to the thermal-, air-, and moisture-related performance of building assemblies. The information can be used in simplified calculation methods as applied in Chapter 27, or in software-based methods for transient solutions. Heat transfer under steady-state and transient conditions is covered in Chapter 4, and Chapter 25 discusses combined heat, air, and moisture transport in building assemblies. For information on thermal insulation for mechanical systems (including insulation used in a range of temperatures), see Chapter 23. For information on insulation materials used in refrigerant piping systems and cryogenic or low-temperature applications, see Chapters 10 and 47 of the 2018 *ASHRAE Handbook—Refrigeration*. For properties of materials not typically used in building construction, see Chapter 33 of this volume.

Density and thermal properties such as thermal conductivity, thermal resistance, specific heat capacity, and emissivity for longwave radiation are provided for a wide range of building materials, insulating materials, and insulating systems. Air and moisture properties (e.g., air permeance, water vapor permeance or permeability, capillary water-absorption coefficients, sorption isotherms) are given for several materials, with a brief description of how to use the tabulated data. Data on soil thermal conductivity, air cavity resistances, and surface film coefficients, which are also important when considering performance of building assemblies, are also provided.

1. INSULATION MATERIALS AND INSULATING SYSTEMS

The main purpose of using thermal insulation materials is to reduce conductive, convective, and radiant heat flows. When properly applied in building envelopes, insulating materials do at least one of the following:

- Increase energy efficiency by reducing the building's heat loss or gain
- Control surface temperatures for occupant comfort
- Help to control temperatures within an assembly, to reduce the potential for condensation
- Modulate temperature fluctuations in unconditioned or partly conditioned spaces

The primary property of a thermal insulation material is a low apparent thermal conductivity. Additional functions may be served, such as providing support for a surface finish, impeding water vapor transmission and air leakage into or out of controlled spaces, reducing damage to structures from exposure to fire and freezing conditions, and providing better control of noise and vibration. These functions, of course, should be consistent with the capabilities of the materials.

ASTM *Standard* C168 defines terms related to thermal insulating materials.

1.1 APPARENT THERMAL CONDUCTIVITY

The primary property of a thermal insulation material is a low apparent thermal conductivity, though selection of the appropriate material for a given application also involves consideration of the other performance characteristics mentioned previously.

Thermal conductivity (symbol k, λ in Europe) is a property of a homogeneous, nonporous material. Thermal insulation materials are highly porous, however, with porosities typically exceeding 90%. As a consequence, heat transmission involves conduction in the solid matrix but mainly gas conduction and radiation in the pores (even convection can occur in larger pores). This is why the term **apparent thermal conductivity** is used. That property is affected by structural parameters such as density, matrix type (fibrous or cellular), and thickness. Each sample of a given insulation material has a unique value of apparent thermal conductivity for a particular combination of temperature, temperature difference, moisture content, and age, a value that is not representative for other conditions. For more details, refer to ASTM *Standards* C168, C177, C335, C518, C976, and C1045.

Influencing Conditions

Density and Structure. Figure 1 shows the variation of the apparent thermal conductivity with density at one mean temperature (i.e., 24°C) for a number of insulation materials used in building envelopes. For most mass-type insulations, there is a minimum that not only depends on the type and form of the material but also on temperature and direction of heat flow. For fibrous materials, the values of density at which the minimum occurs increase as the fiber diameter [or cell size; see Figure 2 (Lotz 1969)] and mean temperature increase.

Structural factors also include compaction and settling of insulation, air permeability, type and amount of binder used, additives that influence the bond or contact between fibers or particles, and type and form of the radiation transfer inhibitor, if any. In cellular materials, most factors that influence strength also control the apparent thermal conductivity: size, shape, and orientation of cells, and thickness of cell walls. As Figures 1 and 2 suggest, a specific combination of cell size, density, and gas composition in those materials produces optimum thermal conductivity.

The preparation of this chapter is assigned to TC 4.4, Building Materials and Building Envelope Performance.

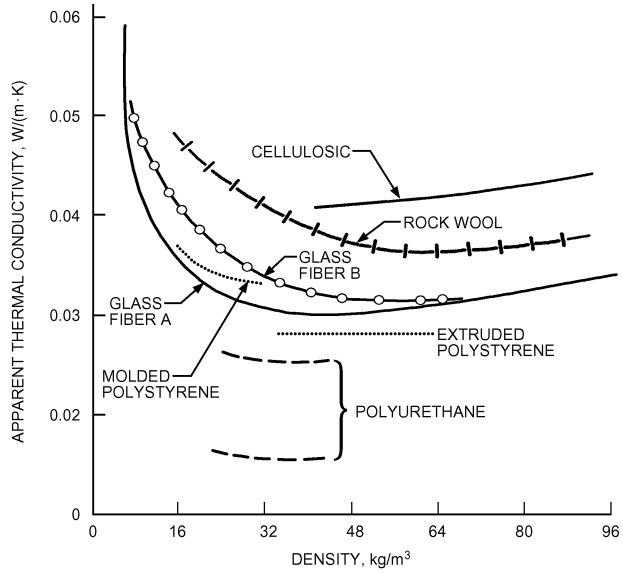

Fig. 1 Apparent Thermal Conductivity Versus Density of Several Thermal Insulations Used as Building Insulations

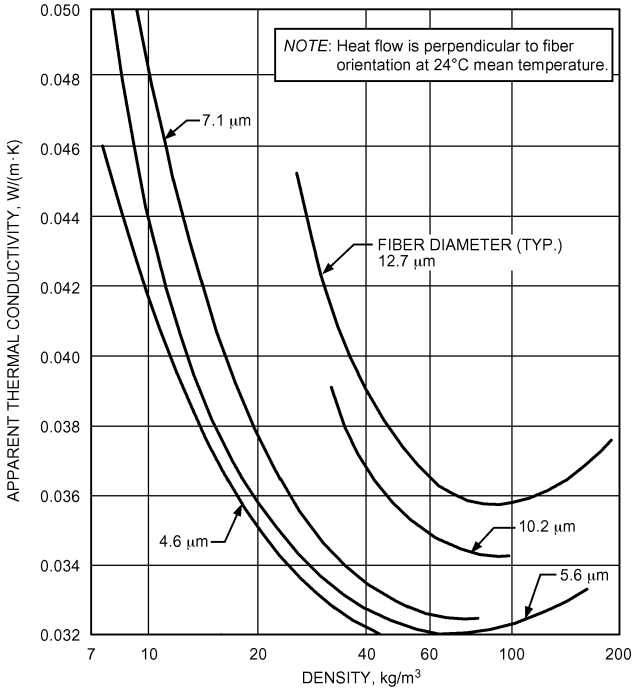

Fig. 2 Variation of Apparent Thermal Conductivity with Fiber Diameter and Density
(Lotz 1969)

Temperature. At most normal operating temperatures, the apparent thermal conductivity of insulating materials generally increases with temperature. The rate of change varies with material type and density. Some materials have an inflection in the curve where the blowing agent changes phase from gas to liquid. The apparent thermal conductivity of a sample at one mean temperature (average of the two surface temperatures) only applies to the material at the particular thickness tested. Further testing is required to obtain values suitable for all thicknesses.

Insulating materials that allow a large percentage of heat transfer by radiation, such as low-density fibrous and cellular products, show the greatest change in apparent thermal conductivity with temperature and surrounding surface emissivity.

The effect of temperature on structural integrity is unimportant for most insulation materials in low-temperature applications. At very low temperatures, however, some polymeric compounds may undergo glass transition, which is characterized by a marked increase in thermal conductivity. For urethanes and butyl-based compounds, this occurs at approximately –40°C, but for silicones the glass transition temperature is more in the range of –90°C, which is not normally encountered in building applications. In any case, decomposition, excessive linear shrinkage, softening, or other effects limit the maximum suitable temperature for a material.

Moisture Content. The apparent thermal conductivity of insulation materials increases with moisture content. If moisture condenses in the insulation, it not only reduces thermal resistance, but it may also physically damage the system, because some insulation materials deteriorate with exposure to water. Most materials would be damaged if moisture were allowed to freeze in the material, because water expands when it freezes. The increase in apparent thermal conductivity depends on the material, temperature, moisture content, and moisture distribution. Section A3 of the *CIBSE Guide A* (CIBSE 2006) covers thermal properties of building structures affected by moisture.

Thickness. Radiant heat transfer in pores of some materials increases the measured apparent thermal conductivity. For low-density insulation (e.g., 5.5 kg/m^3), the effect becomes more pronounced with installed thickness) (Pelanne 1979). The effect on thermal resistance is small, even negligible for building applications. No thickness effect is observed in foam insulation.

Age. As mentioned previously, most heat transfer in insulation materials at temperatures encountered in buildings and outdoors occurs by conduction through air or another gas in the pores (Lander 1955; Rowley et al. 1952; Simons 1955; Verschoor and Greebler 1952). In fact, heat transfer in dry insulation materials can be closely approximated by combining gas conduction with conduction through the matrix and radiation in the pores, each determined separately. If air in the pores of a cellular insulation material is replaced by a gas with a different thermal conductivity, the apparent thermal conductivity changes by an amount approximately equal to the difference between the thermal conductivity of air and the gas. For example, replacing air with an inert gas can lower the apparent thermal conductivity by as much as 50%. Cellular plastic foams with a high proportion (i.e., more than 90%) of closed cells retain the blowing agent for extended periods of time. Newly produced, they have apparent thermal conductivities of approximately 0.022 W/(m·K) at 24°C. This value increases with time as air diffuses into the cells and the gas gradually dissolves in the polymer or diffuses out. Diffusion rates and increase in apparent thermal conductivity depend on several factors, including permeance of cell walls to the gases involved, foam age, temperature, geometry of the insulation (thickness), and integrity of the surface facing or covering provided. Brandreth (1986) and Tye (1988) showed that aging of unfaced polyurethane and polyisocyanurate is reasonably well understood analytically and confirmed experimentally. The dominant parameters for minimum aging are

- Closed-cell content >90%, preferably >95%
- Small, uniform cell diameter <<1 mm
- Small anisotropy in cell structure
- High density
- Increased thickness
- High initial pressure of blowing agent in the cells
- Polymer highly resistant to gas diffusion and solubility

Licensed for single user. © 2021 ASHRAE, Inc.

- Larger proportion of polymer evenly distributed in struts and windows between cells
- Low temperature

For laminated and spray-applied products, aging is further reduced with higher-density polymer skins, or by well-adhered facings and coverings with low gas and moisture permeance. An oxygen diffusion rate of less than 3.5 $mm^3/(m^2 \cdot day)$ for a 25 μm thick facing is one criterion used by some industry organizations for manufacturers of laminated products. Adhesion of the facing must be continuous, and every effort must be made during manufacturing to eliminate or minimize the shear plane layer at the foam/substrate interface (Ostrogorsky and Glicksman 1986).

Before 1987, chlorinated fluorocarbons were commonly used as cell gas. Because of their high ozone-depleting potential, chlorofluorocarbons (CFCs) were phased out during the 1990s in accordance with the Montreal Protocol of 1987. Alternatives used today are fluorinated hydrocarbons, CO_2, *n*-pentane, and *c*-pentane.

Closed-cell phenolic-type materials and products, which are blown with similar gases, age differently and much more slowly because of their closed-cell structure.

Other Influences. Convection and air infiltration in or through some insulation systems may increase heat transfer. Low-density, loose-fill, large open-cell, and fibrous insulation, and poorly designed or installed reflective systems are the most susceptible. The temperature difference across the insulation and the height and width of the insulated space influence the amount of convection. In some cases, natural convection may be inherent to the system (Wilkes and Childs 1992; Wilkes and Rucker 1983), but in many cases it is a consequence of careless design and/or construction of the insulated structure (Donnelly et al. 1976). Gaps between board- and batt-type insulations lower their effectiveness. Board-type insulation may not be perfectly square, may be installed improperly, and may be applied to uneven surfaces. A 4% void area around batt insulation can produce a 50% loss in effective thermal resistance for ceiling application with $R = 3.4$ $(m^2 \cdot K)/W$ (Verschoor 1977). Similar and worse results have been obtained for wall configurations (Brown et al. 1993; Hedlin 1985; Lecompte 1989; Lewis 1979; Rasmussen et al. 1993; Tye and Desjarlais 1981). As a solution, preformed joints in board-type insulation allow boards to fit together without air gaps. Boards and batts can be installed in two layers, with joints between layers offset and staggered. The requirements of ASHRAE *Standard* 90.1 provide additional guidance on proper installation of insulating materials, as does Chapter 45 in the 2019 *ASHRAE Handbook—HVAC Applications*.

Measurement. Apparent thermal conductivity for insulation materials and systems is obtained by the measuring methods listed in ASTM (2008). These methods apply mainly to laboratory measurements on dried or conditioned samples at specific mean temperatures and temperature gradient conditions. Although fundamental heat transmission characteristics of a material or system can be determined accurately, actual performance in a structure may vary from laboratory results. Only field measurements can clarify the differences. Field-test procedures continue to be developed. Envelope design, construction, and material may all affect the procedure to be followed, as detailed in ASTM (1985a, 1985b, 1988, 1990, 1991).

1.2 MATERIALS AND SYSTEMS

Glass Fiber and Mineral Wool

Glass fiber is produced using recycled glass, whereas mineral wool uses diabase stone. Glass and stone are melted, after which a spinning head stretches the melt into fibers with diameter <10 μm. These fall through a spray of phenol or silicon binder onto the facings for blankets and batts, which lie on a conveyor belt. The fiber blankets, batts, or boards pass a heated press where the binder hardens and the insulation gets its final density and thickness. After passing through the press, the blankets, batts, or boards are cut to size. The spectrum of finished products includes loose fill; over blankets and batts; and soft, semidense, and dense boards. Blankets cannot take any extra load, except their own weight. Dense boards are moderately compression resistant, with a modulus of σ_{10}, or about 0.04 to 0.08 MPa.

Mineral wool and glass fiber may look similar, but there are important differences. Glass fiber consists of well-ordered, long fibers, whereas mineral wool is composed of unordered, shorter fibers. Glass is also amorphous, whereas diabase stone is crystalline.

The thermal conductivity of glass fiber is somewhat lower than for mineral wool (see Table 1), with lower values for higher-density blankets in both materials. Glass and mineral fiber are very vapor permeable. The coefficient of thermal expansion is low for both materials, at ~7×10^{-6} K^{-1}, and irreversible hygrothermal deformation does not occur. The two are also very temperature resistant, although the binder may start evaporating above 250°C and degrades above 600°C for glass fiber and above 850°C for mineral wool (consequently, mineral wool is preferred for high-temperature applications). Both insulation materials are quite moisture tolerant, although wet batts and blankets lose their shape, and the stiffness and compression strength of some dense boards degrade when wet. Glass fibers slowly pulverize when exposed to a combination of high temperature, moisture, and oxygen. Neither glass fiber nor mineral wool burn, but the binder may be combustible. Binder concentrations below 4% simply evaporate, but more concentrated binders can burn. Also, most facing layers are flammable.

Glass fiber and mineral wool are widely used insulation materials. Applications range from low-slope roofs (dense boards) and pitched roofs (blankets, batts, and soft boards) to cavity fill (semidense water-repellant boards), timber-frame insulation, exterior insulation finishing systems (EIFS) (dense boards), floor insulation (dense boards), and perimeter insulation (dense boards). Manufacturers modify specific products for many applications, including boards with improved water-repellent properties for full-cavity fill and boards with a dense upper layer for low-slope roofing.

Cellulose Fiber

The base material for cellulose fiber is unsold or recycled newspaper and cardboard. Borax salts are added during processing to reduce flammability and mold sensitivity. The material is available in loose form, and is placed into the desired space by wet or dry blowing, which results in densities between 24 to 60 kg/m^3, depending on blowing pressure. The material is also available in board form.

Cellulose fibers are very hygroscopic, and the borax salt magnifies that property. The fibers are also capillary active, and quite vapor permeable. Avoid loading beyond the mass of a loose fill. Less densely packed cellulose fibers show irreversible settling and are sensitive to hygric swelling and shrinking; wet-blown fibers exhibit shrinkage upon drying. Long-lasting moisture content above 20% (as a percentage of dry mass) should be avoided, because this ultimately leads to decay. Despite the borax salts, cellulose fibers are rather combustible. The borax salts are also not benign: simple exposure may cause respiratory and skin irritation, and ingestion could induce gastrointestinal distress (including nausea, persistent vomiting, abdominal pain, and diarrhea); less common effects on the vascular system and brain are headaches and lethargy.

Cellulose fibers are typically used as an alternative for glass fiber and mineral wool. Typical applications are insulation of timber-framed walls, and insulation of the ceiling between living spaces and attics. The boards are used for insulating pitched roofs. One important limitation: never apply cellulose fiber (or any insulation, for that matter) where continued long-term wetness may be expected.

Licensed for single user. © 2021 ASHRAE, Inc.

Plastic Foams

Expanded Polystyrene (EPS). The basic material for EPS is pentane-blown polystyrene pearls. The pearls are first heated above 100°C, at which temperature the evaporating pentane causes expansion. The expanded pearls are then stored for a few days, allowing diffusion of the remaining pentane. Then they are poured into molds and steam heated, so that the expanded pearls coagulate in their own melt. Once cool, the blocks are cut into boards and stored until initial shrinkage ends. EPS is a thermoplastic with a problematic fire reaction: it melts and drips when burning. Consequently, additives are used to slow down flammability.

Extruded Polystyrene (XPS). The basic material for XPS is polystyrene pearls, which are melted, blown with a blowing agent, and extruded into boards with a dense skin. The extruded foam is then stabilized in a water bed and cut into separate boards. As with EPS, XPS is stored for several weeks before application. XPS is also a thermoplastic with additives used to slow down flammability. The water vapor resistance of XPS boards is very high, allowing their use in inverted roofs and as perimeter insulation in humid soils.

Polyurethane (PUR and Polyisocyanurate (PIR). PUR and PIR are the only insulation materials produced chemically by isocyanate reacting with polyolefin in the presence of a catalyst, a blowing agent, and additives. The difference between the two is the isocyanate ratio: in PIR, this ratio is high enough (60 to 65% kg/kg instead of 50 to 55% kg/kg) to form autopolymers. The main result is a better reaction in combustion. Because the explosive isocyanate/polyolefin reaction is highly sensitive to temperature and relative humidity, strict control of both parameters is needed. The reaction product is also very sticky, which allows the mixture to be sprayed on many kinds of substrates, or to be used to produce sandwich panels (Figure 3). Once the reaction is finished, the boards are cut to the desired size and stored.

R-11 [a CFC with ozone depletion potential (ODP) = 1] was used as a blowing agent until the early 1990s. Since then, blowing agents with zero ODP are preferred, such as hydrofluorocarbons (HFCs) for PUR insulation boards, HFCs or CO_2 for spray-applied PUR, and pentane for PIR boards.

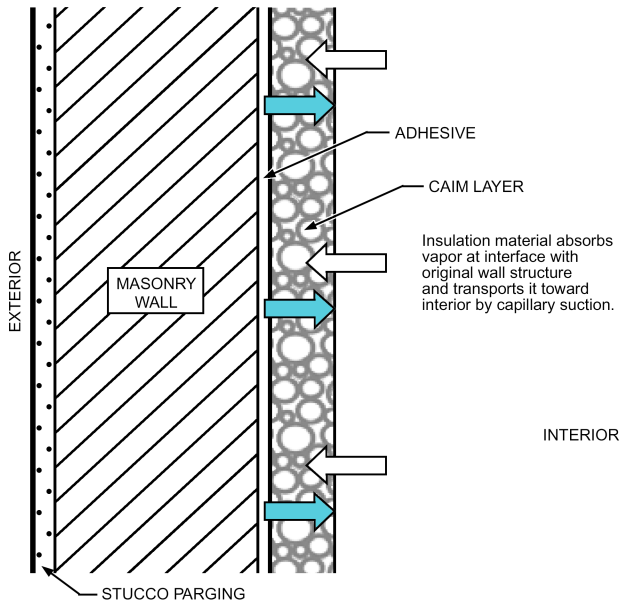

Fig. 3 Working Principle of Capillary-Active Interior Insulation

Cellular Glass

Cellular glass is a light, expanded-glass insulation with closed-cell pores. It is water- and vaportight, allowing neither vapor diffusion nor capillary suction through the material. Depending on the production process, cellular glass is delivered either as insulating boards or as loose-fill aggregate. The boards are used for roof, wall, basement, and foundation insulation; loose fill is only used for foundation or basement insulation. Cellular glass boards must be protected from frost damage caused by water freezing in its open surface pores. The R-value of cellular glass boards is not affected by moisture, but the thermal resistance of loose fill decreases in moist conditions because of water clinging to the surface of the aggregates.

Capillary-Active Insulation Materials (CAIMs)

CAIMs are used as interior wall insulation for existing buildings. Despite being rather vapor permeable, they are applied without a vapor-retarding layer because condensing moisture is supposed to be wicked away from the dew point toward the interior wall surface (Figure 3). In contrast to conventional insulation systems that need a vapor retarder to protect the wall structure from harmful condensation, CAIMs provide condensation control without reducing the drying potential towards the indoors. Because of increasing demand in Europe, several capillary-active insulation systems made of calcium silicate, foamed concrete, or hydrophilic glass fiber have appeared on the market. Tests [e.g., (Zhao et al. (2017)] show that these materials may differ in their wicking ability, but most of them succeed in redistributing condensate by capillary suction. However, even the best-performing CAIM cannot prevent increased relative humidity at the interface between interior insulation and original wall surface of 95% or more in winter (Binder et al. 2010). The benefits of CAIMs for insulating existing wall structures are therefore still debatable. Other potential concerns are that their thermal resistances are also generally inferior to those of conventional insulation [k = 0.05 to 0.06 W/(m·K)].

Transparent Insulation

Transparent insulation material (TIM) combines transparency for short-wave radiation with low heat conduction, extremely low convection, and opacity for long-wave radiation. The material comprises thin parallel transparent plastic tubes or transparent glass fibers sandwiched between two glass sheets. TIM has a higher thermal conductivity than classic insulation materials [between 0.049 and 0.063 W/(m·K)] but allows solar gains into the conditioned space, so the net heat balance (equilibrium between losses and gains) may be more favorable.

Still, use of this material remains limited because of soiling and overheating. The plastic tubes slowly yellow, and, if the space between the two glass sheets is not vaportight, water vapor may diffuse into the panels and condense against the coldest sheet. Dust may enter the TIM boards through spacer leaks and be fixed in the condensate. Also the exterior surface of the panels can become soiled. Overheating is moderated by combining the TIM with solar shading, but this is currently too expensive to be economically viable.

Vacuum Insulation Panels

Vacuum insulation (sometimes called **modified-atmosphere insulation** because the interior is not a hard vacuum) is available in rigid and semirigid panels of various sizes. Vacuum insulation panels consist of an interior filler material and an exterior barrier material. Heat conduction through the center of the panel is typically less than 0.007 W/(m·K); some panels have been manufactured with a center-of-panel thermal conductivity less than 0.0025 W/(m·K) However, heat is also transported around the edges of the panel, and that heat transport (often referred to as **edge effect**) can significantly reduce the thermal resistance of the whole panel compared to the thermal

resistance of the center region. For that reason, the resistance of the whole assembly should be considered, and larger panels are generally preferred. In buildings, vacuum panels may be used when the space available for thermal insulation is tightly constricted, such as in historic building retrofits. Vacuum insulation panels are also used in appliances and shipping containers.

Vacuum insulation panels rely on reduced gaseous conduction, via reduced air pressure, for their thermal performance and must therefore be protected from puncture or other physical damage. Depending on the permeability of the barrier material and the nature of the seam joining the barrier material around the unit's perimeter, panels age through air diffusion. To delay this phenomenon, most barrier materials incorporate a very thin metallic layer (often produced using vapor deposition methods). Another way to slow aging is to incorporate getter materials (i.e., any reactive material that absorbs small amounts of gas in an evacuated space) within the panel; some filler materials act as getters themselves. The filler material supports the exterior atmospheric pressure load on the panel and reduces both radiative and gaseous heat transport across the panel. To reduce gaseous heat transfer, voids in the filler material must be smaller than the mean free path of the gas molecules, which is in turn determined by the air pressure in the panel. Therefore, filler materials with finer void sizes retain their heat transfer reduction abilities at higher pressures than fillers with greater void sizes do.

Reflective Insulation Systems

Reflective insulation consists of surfaces having high reflectivity (and low emissivity) for long-wave radiation, thus reducing radiant heat transfer. To be effective, these surfaces must face an air layer, or no radiant heat transfer is available to be reduced. Conventional calculation methods ascribe the radiative properties to the facing air layer, rather than to the reflective insulation system, to avoid double-counting the reflective effect. Multiple layers of reflective materials facing smooth and parallel sealed air spaces increase overall thermal resistance, though thermal conductivity will never be less than that of still air. In any case, air exchange and movement must be inhibited or the reduction in radiative heat transfer will be overshadowed by increased convection.

Conventional insulation can be combined with reflective surfaces facing air spaces to increase thermal resistance. However, each design must be evaluated, because thermal performance of these systems depends on factors such as condition of insulation, shape and form of construction, means to avoid air leakage and movement, and condition and aging characteristics of reflective surfaces.

Values for foil insulation products supplied by manufacturers must be used with caution because they apply only to systems that are identical to the configuration in which the product was tested. In addition, surface oxidation, dust accumulation, condensation, and other factors that change the condition of the low-emittance surface can reduce the thermal effectiveness (Hooper and Moroz 1952). Deterioration results from contact with acidic or basic solutions (e.g., wet cement mortar, preservatives found in decay-resistant lumber). Polluted environments may cause rapid and severe degradation. However, Hooper and Moroz found that site inspections showed a predominance of well-preserved reflective surfaces, with only a small number of cases of rapid and severe deterioration. An extensive review of the reflective building insulation system performance literature is provided by Goss and Miller (1989).

2. AIR BARRIERS

The main characteristic of an air barrier system is reduced air permeance. To create that performance, the barrier must

- Meet material permeability requirements.
- Be continuous when installed (i.e., tight joints in air barrier assembly; effective bonds in air barrier materials at intersections such as wall/roof, wall/foundation, and wall/windows; tightly sealed penetrations).
- Accommodate dimensional changes caused by temperature or shrinkage without damaging joints or air barrier material.
- Be strong enough to support stresses applied to air barrier material or assembly. The air barrier must not be ruptured or excessively deformed by wind and stack effect. Where an adhesive is used to complete a joint, the assembly must be designed to withstand forces that might gradually peel away the air barrier material. Where the material is not strong enough to withstand anticipated wind and other loads, it must be supported on both sides to account for positive and negative wind gust pressures.

In addition, the following properties can be important, depending on the application:

- Elasticity
- Thermal stability
- Fire and flammability resistance
- Inertness to deteriorating elements
- Ease of fabrication, application, and joint sealing

Air barriers may control both vapor and airflow (i.e., they may act as an air/vapor retarder), depending on the characteristics of the materials used. Many designs are based on this idea, with measures taken to ensure that the layer with vapor-retarding properties is continuous to control airflow. Some designs treat airflow and vapor retarders as separate entities, but an airflow retarder should not be where it can cause moisture to condense if it also has vapor-retarding properties. For example, a vapor-retarding air barrier placed on the cold side of a building envelope may cause condensation, particularly if the vapor retarder at the other side of the building is ineffective. Instead, a carefully installed, sealed cold-side air retarder that has sufficient thermal resistance may lower the potential for condensation by raising the temperature at its inside surface during the cold season (Ojanen et al. 1994).

Air leakage characteristics can be determined with the ASTM *Standard* E1186 test method for air barriers on the interior side of the building envelope, and described according to ASTM *Standard* E1677. Specific air leakage criteria for air barriers in cold heating climates are found in Di Lenardo et al. (1995). These specifications provide classes for air leakage rates of 0.05, 0.10, 0.15, and 0.20 L/(s·m^2) when measured with an air pressure difference of 75 Pa, depending on the water vapor permeance of the outermost layer of the building envelope. The highest leakage rate applies if the permeance of the outermost layer is greater than 600 ng/(Pa·s·m^2); the lowest rate applies if the permeance is less than 60 ng/(Pa·s·m^2). Intermediate values are also provided. The recommendations apply only to heating climates.

The required air permeance of an air barrier material has been set by some building codes at 0.02 L/(s·m^2) at a pressure difference of 75 Pa. A 2008 addendum to ASHRAE *Standard* 90.1 also references this value. ASTM *Standard* E1677 provides an alternative minimum air barrier test and criteria specifically suitable for framed walls of low-rise buildings.

Air leakage characteristics of an air barrier assembly can be determined with the ASTM *Standard* E2357 test method, which measures the air leakage of three wall specimens: (1) with the air barrier material installed using air barrier accessories alone, (2) with the air barrier material installed and connected to air barrier components (window, doors, and other premanufactured elements) using air barrier accessories, and (3) with an air barrier wall assembly connected to a foundation assembly and roof assembly using air barrier accessories. The test method reports the air leakage rate at a reference pressure difference of 75 Pa, not because it is necessarily

Licensed for single user. © 2021 ASHRAE, Inc.

representative of in-service conditions, but because it provides a more accurate measurement that can then be adjusted for actual conditions.

Building assemblies are constructed and the various air barrier assemblies are connected to form an air barrier system for the whole building. The building's air leakage characteristics can be determined with the ASTM *Standard* E779 test method. A 2008 addendum to ASHRAE *Standard* 90.1 requires 2.0 L/(s·m^2) at 75 Pa pressure difference.

The effectiveness of an air barrier is greatly reduced by openings and penetrations, even small ones. These openings can be caused by poor design, poor workmanship during application, insufficient coating thickness, improper caulking and flashing, uncompensated thermal expansion, mechanical forces, aging, and other forms of degradation. Faults or leaks typically occur at electrical boxes, plumbing penetrations, telephone and television wiring, and other unsealed openings in the structure. This is especially true if telephone, television, or other services are installed after the envelope has been inspected and/or tested. A ceiling air barrier should be continuous at chases for plumbing, ducts, flues, and electrical wiring. In flat roofing, mechanical fasteners are sometimes used to adhere the system to the deck, and often penetrate the air barrier. In heating climates, the resulting holes may allow air exfiltration and accompanying water vapor leakage into the roof. ASTM *Standard* E1186 describes several techniques for locating air leakage sites in building envelopes and air barrier systems.

As noted previously, air barrier assemblies must withstand pressures exerted by stack effects, wind, or both during construction and over the building's life. The magnitude of pressure varies, depending on building type and sequence of construction. At one extreme, single-family dwellings may be built with exterior cladding partly or entirely installed and insulation in place before the air barrier is added. Chimney effects in these buildings are small, even in cold weather, so stresses on the air barrier during construction are small. At the other extreme, wind and chimney effect forces in tall buildings are much greater. A fragile, unprotected sheet material should not be used as an air barrier because it will probably be torn by wind before construction is completed.

Calculations of water vapor flow, interstitial condensation, and related moisture accumulation using only water vapor resistances are useless when airflow is involved. More information on air leakage in buildings may be found in Chapter 16.

3. WATER VAPOR RETARDERS

The main characteristic of a water vapor retarder is low vapor permeance. The following properties are also important, depending on the application:

- Mechanical strength in tension, shear, impact, and flexure
- Adhesion
- Elasticity
  Thermal stability
- Fire and flammability resistance
- Resistance to other deteriorating elements [e.g., chemicals, ultraviolet (UV) radiation]
- Ease of fabrication, application, and joint sealing

Although a flow of dry air may accelerate drying of a wet building component (Karagiozis and Salonvaara 1999a, 1999b), vapor retarders are completely ineffective without effective airflow control, A single layer may serve both purposes, of course: the designer must assess the needs for control of water vapor and air movement in a building envelope, and devise a system that guarantees the required vapor retarder and air barrier properties.

Water vapor retarders demand consideration in every building design. The need for and type of system depend on the climate zone, construction type, building usage, and moisture sources other than indoor water vapor to be considered. Water vapor retarders were originally designed to protect building elements from water vapor diffusing through building materials and condensing against and in layers at the cold side of the thermal insulation. It is now recognized that it is just as important to allow a building assembly to dry as it is to keep the building assembly from getting wet by vapor diffusion. In some cases, to allow the building assembly to dry, a water vapor retarder may not be needed, or should be semipermeable. In other cases, the environmental conditions, building construction, and building usage may dictate that a material with very low water vapor permeance should be installed to protect building components. A balanced design approach is required: a vapor retarder can reduce the potential for an assembly to dry, but can also reduce the potential for the assembly getting wet. ASHRAE *Standard* 160 should be followed to determine the need for and placement of a vapor retarder.

The 2007 supplement to the International Codes (ICC 2007) lists three water vapor retarder classes:

- **Class I:** 5.7 ng/(Pa·s·m^2) or less
- **Class II:** more than 5.7 ng/(Pa·s·m^2) but less than or equal to 57 ng/(Pa·s·m^2)
- **Class III:** more than 57 ng/(Pa·s·m^2) but less than or equal to 570 ng/(Pa·s·m^2)

The designer should determine the type of water vapor retarder needed and its location in the envelope assembly, based on climatic conditions, other materials used in the assembly, additional sources of humidity, and the building's use (e.g., intended relative humidity).

A vapor retarder typically slows the rate of water vapor diffusion, but does not totally prevent it. In most cases, requirements for vapor retarders in envelope assemblies are not extremely stringent: because conditions on the inside and outside of buildings vary continually, air movement and ventilation can provide wetting as well as drying at various times, and water vapor entering one side of an envelope assembly can be stored temporarily as hygroscopic moisture and released later. A vapor barrier is often used to try to stop water vapor transport when the real problem is transport of water vapor by air transport. This causes confusion between the use and function of vapor barriers/retarders and those of air barriers. However, if conditions are conducive to excessive humidification, water vapor retarders help to (1) keep the thermal insulation dry; (2) prevent structural damage from rot, corrosion, freeze/thaw, and other environmental actions; and (3) reduce paint problems on exterior walls (although rain absorption through cracks in the paint may be a more probable cause of paint problems) (ASTM *Standard* C755). Judicious placement of a vapor retarder may also help an assembly to dry out. Another way to look at a vapor retarder is that it is the most vapor-resistant layer in the assembly; a capable designer knows where this layer is and ensures that it does not promote excessive moisture accumulation or prevent the assembly from drying. Therefore, all building envelope assemblies should be assessed to ensure that an unintentional water vapor retarder does not create problems.

The vapor retarder's effectiveness depends on its vapor permeance, installation, and location in the insulation. The retarder should be at or near the surface exposed to higher water vapor pressure and higher temperature. In heating climates, this is usually the winter-warm side.

Water vapor retarders are classified as rigid, flexible, or coating materials. **Rigid retarders** include reinforced plastics, aluminum, and stainless steel. These usually are mechanically fastened in place and are vapor-sealed at the joints. **Flexible retarders** include metal foils, laminated foil and treated papers, coated felts and papers, and plastic films or sheets. They are supplied in roll form or as an integral part of a building material (e.g., insulation). Accessory materials are required for sealing joints. **Coating retarders** may be

Licensed for single user. © 2021 ASHRAE, Inc.

semifluid or mastic; paint (called surface coatings); or hot melt, including thermofusible sheet materials. Their basic composition may be asphaltic, resinous, or polymeric, with or without pigments and solvents, as required to meet design conditions. They can be applied by spray, brush, trowel, roller, dip, or mop, or in sheet form, depending on the type of coating and surface to which it is applied. Potentially, each of these materials is an air barrier; however, to meet air barrier specifications, it must satisfy requirements for strength, continuity, and air permeance. A construction of several materials, some perhaps of substantial thickness, can also constitute a vapor retarder system. In fact, designers have many options. For example, airflow and moisture movement might be controlled using an interior finish, such as drywall, to provide strength and stiffness, along with a low-permeability coating, such as a vapor-retarding paint, to provide the required low permeance. Other designs may use more than one component. However, (1) any component that qualifies as a vapor retarder usually also impedes airflow, and is thus subject to air pressure differences that it must resist; and (2) any component that impedes airflow may also retard vapor movement and promote condensation or frost formation if it is at the wrong location in the assembly.

Several studies found a significant increase in apparent permeance as a result of small holes in the vapor retarder. For example, Seiffert (1970) reported a hundredfold increase in the vapor permeance of aluminum foil when it is 0.014% perforated, and a 4000-fold increase when 0.22% of the surface is perforated. In general, penetrations particularly degrade a vapor retarder's effectiveness if it has very low permeance (e.g., polyethylene or aluminum foil). In addition, perforations may lead to air leakage, which further erodes effectiveness.

"Smart" vapor retarders allow substantial summer drying while functioning as effective vapor retarders during the cold season. One type of smart vapor retarder has low vapor permeance but conducts liquid water, allowing moisture that condenses on the retarder to dry. Korsgaard and Pedersen (1989, 1992) describe such a retarder composed of synthetic fabric sandwiched between staggered strips of plastic film. The fabric wicks liquid water while the plastic film retards vapor flow. Another type of smart vapor retarder provides low vapor permeance at low relative humidities, but much higher permeance at high relative humidity. During the heating season in cold and moderate climates, the indoor humidity usually is below 50% and the smart vapor retarder's permeance is low. In the summer or on winter days with high solar heat gains, when the temperature gradient is inward, moisture moving from exterior parts of the wall or roof raises the relative humidity at the vapor retarder. This increases vapor permeance and potential for the wall or roof to dry out. One such vapor retarder is described by Kuenzel (1999). Below 50% rh, the film's permeance is less than 57 ng/(Pa·s·m^2), but it increases above 60% rh, reaching 2050 ng/(Pa·s·m^2) at 90% rh.

4. DATA TABLES

4.1 THERMAL PROPERTY DATA

Steady-state thermal resistances (R-values) of building assemblies (walls, floors, windows, roof systems, etc.) can be calculated from thermal properties of the materials in the component, provided by Table 1, or heat flow through the assembled component can be measured directly with laboratory equipment such as the guarded hot box (ASTM *Standard* C1363). Direct measurement is the most accurate method of determining the overall thermal resistance for a combination of building materials combined as a building envelope assembly. However, not all combinations may be conveniently or economically tested in this manner. For many simple constructions, calculated R-values (see Chapter 25) agree reasonably well with values determined by hot-box measurement.

Values in Table 1 were developed by testing under controlled laboratory conditions. In practice, overall thermal performance can be reduced significantly by factors such as improper installation, quality of workmanship and shrinkage, settling, or compression of the insulation (Tye 1985, 1986; Tye and Desjarlais 1983). Good workmanship becomes increasingly important as the insulation requirement becomes greater. Therefore, some engineers include additional insulation or other safety factors based on experience in their design

Values in Table 1 are recorded at 24°C, and are intended to be representative values of generic materials. The tabulated thermal conductivities are either relatively constant as tested, or vary over a range of densities. For the most part, thermal conductivity varies directly with density, which provides some guidance for users here a range is presented. A conservative design might use values at the higher end of the range (unless moisture content is a concern, in which case low-conductivity materials might reduce the assembly's ability to dry out, and would thus be a more conservative choice). References are provided for each material, so users can investigate the as-tested conditions, and additional information regarding the test specimens.

Caution: values in Table 1 should not be used without referring to the footnotes, which define limitations and some of the as-tested conditions for the materials listed.

Because commercially available materials vary, not all values apply to specific products.

4.2 SURFACE EMISSIVITY AND EMITTANCE DATA

Table 2 provides measured long-wave emissivities for various surfaces, which are used to characterize radiant heat transfer to or from these surfaces. To simplify radiant heat transfer calculations, the combined emittance for two surfaces is also provided, although these values can be calculated using $\varepsilon_{eff} = 1/(1/\varepsilon_1 + 1/\varepsilon_2 - 1)$. As described previously, surface oxidation, dust accumulation, condensation, and other factors can impair the emissivity of highly reflective surfaces, so slightly higher values should be used.

4.3 THERMAL RESISTANCE OF PLANE AIR SPACES

Table 3 provides effective resistance values for plane (i.e., generally flat) air spaces that are enclosed within an assembly. Where an assembly incorporates reflective insulation, the effect of the reflective surface is ascribed to the air space, not to the material component. It should be understood that the reflective surface must face an air space to have any effect in reducing thermal transmittance, and assigning the value of the reflective surface to the air space in a design calculation reinforces this concept. Note that "reflective insulation systems" are bounded by an enclosed air space within an assembly, whereas "radiant barrier systems" feature a reflective surface facing an open airspace. Reflective insulation may be described as modifying the effective R-value of the assembly, but a radiant barrier system may not. This includes reflective surfaces behind siding, which should not be considered as "reflective insulation" (in most cases, the nature of the heat transfer will be dominated by wind-driven convection, rather than radiant exchange). Thermal resistance values for siding with reflective foil backing are provided in Table 1.

4.4 AIR PERMEANCE DATA

Table 4 provides measured air permeability of different materials, tested in accordance with Bomberg and Kumaran (1986), to be used in assessing the suitability of these materials in an air barrier assembly. As discussed previously, low air permeance is not sufficient to

Notes for Table 1

[a]Values are for mean temperature of 24°C. Representative values for dry materials are intended as design (not specification) values for materials in normal use. Thermal values of insulating materials may differ from design values depending on in situ properties (e.g., density and moisture content, orientation, etc.) and manufacturing variability. For properties of specific product, use values supplied by manufacturer or unbiased tests.

[b]Symbol λ also used to represent thermal conductivity.

[c]Does not include paper backing and facing, if any. Where insulation forms boundary (reflective or otherwise) of airspace, see Tables 2 and 3 for insulating value of airspace with appropriate effective emittance and temperature conditions of space.

[d]Conductivity varies with fiber diameter (see Chapter 25). Batt, blanket, and loose-fill mineral fiber insulations are manufactured to achieve specified R-values, the most common of which are listed in the table. Because of differences in manufacturing processes and materials, the product thicknesses, densities, and thermal conductivities vary over considerable ranges for a specified R-value.

[e]Values are for aged products with gas-impermeable facers on the two major surfaces. An aluminum foil facer of 25 µm thickness or greater is generally considered impermeable to gases. For change in conductivity with age of expanded polyisocyanurate, see SPI Bulletin U108.

[f]Cellular phenolic insulation may no longer be manufactured.

[g]Insulating values of acoustical tile vary, depending on density of board and on type, size, and depth of perforations.

[h]Values for fully grouted block may be approximated using values for concrete with similar unit density.

[i]Values for concrete block and concrete are at moisture contents representative of normal use.

[j]Values for metal or vinyl siding applied over flat surfaces vary widely, depending on ventilation of the airspace beneath the siding; whether airspace is reflective or nonreflective; and on thickness, type, and application of insulating backing-board used. Values are averages for use as design guides, and were obtained from several guarded hot box tests (ASTM *Standard* C1363) on hollow-backed types and types made using backing of wood fiber, foamed plastic, and glass fiber. Departures of ±50% or more from these values may occur.

[k]Vinyl specific heat = 1.0 kJ/(kg·K)

[l]See Adams (1971), MacLean (1941), and Wilkes (1979). Conductivity values listed are for heat transfer across the grain. Thermal conductivity of wood varies linearly with density, and density ranges listed are those normally found for wood species given. If density of wood species is not known, use mean conductivity value. For extrapolation to other moisture contents, the following empirical equation developed by Wilkes (1979) may be used:

$$k = 0.1791 + \frac{(1.874 \times 10^{-2} + 5.753 \times 10^{-4} M)\rho}{1 + 0.01M}$$

where ρ is density of moist wood in kg/m³, and M is moisture content in percent.

[m]Dimension referenced is taken at the maximum siding profile thickness. The range of R values and associated thicknesses represent values for products tested to ASTM *Standard* D7793, which requires applying 6.7 m/s airstream perpendicular to surface of siding during testing.

[n]From Wilkes (1979), an empirical equation for specific heat of moist wood at 24°C is as follows:

$$c_p = \frac{(0.299 + 0.01M)}{(1 + 0.01M)} + \Delta c_p$$

where Δc_p accounts for heat of sorption and is denoted by

$$\Delta c_p = M(1.921 \times 10^{-3} - 3.168 \times 10^{-5} M)$$

where M is moisture content in percent by mass.

[o]Blank space in reference column indicates historical values from previous volumes of *ASHRAE Handbook*. Source of information could not be determined.

ensure a reliable air barrier assembly: the system must be properly fastened and supported (on both sides) to resist wind loads, and all materials must be durable for the expected service life of the assembly. The air barrier must also be continuous, and should be installed in such a way as to discourage wind washing (i.e., air movement that reduces the thermal resistance of insulation layers in the assembly).

4.5 WATER VAPOR PERMEANCE DATA

Table 5 gives typical water vapor permeance and permeability values for common building materials. These values can be used to calculate water vapor flow through building components and assemblies using equations in Chapter 25.

Water vapor permeability of most building materials is a function of moisture content, which, in turn, is a function of ambient relative humidity. Permeance values at various relative humidities are presented in Table 6 for several building materials. Figure 4 depicts the increase in permeability with increasing relative humidity for oriented strand board (OSB) and plywood samples (Kumaran 2002).

Users of the dew-point method may use constant values found in Table 5. However, if condensation in the assembly is predicted, then a more appropriate value should be used. Transient hygrothermal modeling typically uses vapor permeability values that vary with relative humidity. Vapor permeability of homogeneous materials can be calculated from thickness and vapor permeance (as given in Table 6).

Table 2 Emissivity of Various Surfaces and Effective Emittances of Facing Air Spaces[a]

Surface	Average Emissivity ε	Effective Emittance ε_{eff} of Air Space: One Surface's Emittance ε; Other, 0.9	Effective Emittance ε_{eff} of Air Space: Both Surfaces' Emittance ε
Aluminum foil, bright	0.05	0.05	0.03
Aluminum foil, with condensate just visible (>0.5 g/m²)	0.30[b]	0.29	—
Aluminum foil, with condensate clearly visible (>2.0 g/m²)	0.70[b]	0.65	—
Aluminum sheet	0.12	0.12	0.06
Aluminum-coated paper, polished	0.20	0.20	0.11
Brass, nonoxidized	0.04	0.038	0.02
Copper, black oxidized	0.74	0.41	0.59
Copper, polished	0.04	0.038	0.02
Iron and steel, polished	0.2	0.16	0.11
Iron and steel, oxidized	0.58	0.35	0.41
Lead, oxidized	0.27	0.21	0.16
Nickel, nonoxidized	0.06	0.056	0.03
Silver, polished	0.03	0.029	0.015
Steel, galvanized, bright	0.25	0.24	0.15
Tin, nonoxidized	0.05	0.047	0.026
Aluminum paint	0.50	0.47	0.35
Building materials: wood, paper, masonry, nonmetallic paints	0.90	0.82	0.82
Regular glass	0.84	0.77	0.72

[a]Values apply in 4 to 40 μm range of electromagnetic spectrum. Also, oxidation, corrosion, and accumulation of dust and dirt can dramatically increase surface emittance. Emittance values of 0.05 should only be used where the highly reflective surface can be maintained over the service life of the assembly. Except as noted, data from VDI (1999).

[b]Values based on data in Bassett and Trethowen (1984).

4.6 MOISTURE STORAGE DATA

Transient analysis of assemblies requires consideration of the materials' moisture storage capacity. Some materials (**hygroscopic**) adsorb or reject moisture to achieve equilibrium with adjacent air. Storage capacity of these materials is typically shown by graphs of moisture content versus humidity. The curve showing uptake of moisture (the **sorption isotherm**) is usually above the curve showing drying (the **desorption isotherm**) because the material's uptake and release of moisture are inhibited by surface tension. Table 7 provides data for these curves for several hygroscopic materials, and Kumaran (1996, 2002) and McGowan (2007) provide actual curves, additional data, and conditions under which they were determined.

Table 7 expresses moisture content as percentage of dry mass, followed by a subscript value of the relative air humidity at which this moisture content occurs. Note that these values are based on measurement of materials that have reached equilibrium with their surroundings, which in some cases can take many weeks. Most hygrothermal simulation software programs that use these values assume that equilibrium is achieved instantaneously.

Maximum values in Table 7 are those that could be realistically measured in laboratory conditions, so not all materials have a listing for maximum moisture content at 100% relative humidity. For those that do, there may be two listings: the moisture content measured when the material's capillary pores were saturated (shown as 100c), and the value at total saturation (shown as 100t). Note that the moisture content of any material is 0.0 at a theoretical relative humidity of 0%, so this point is not shown in the table.

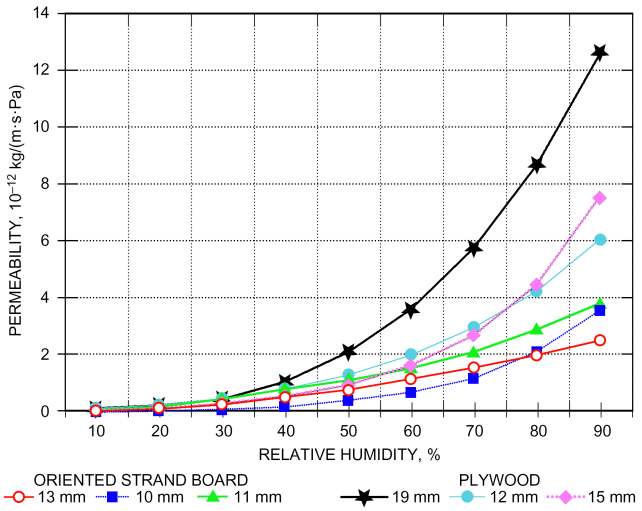

Fig. 4 Permeability of Wood-Based Sheathing Materials at Various Relative Humidities

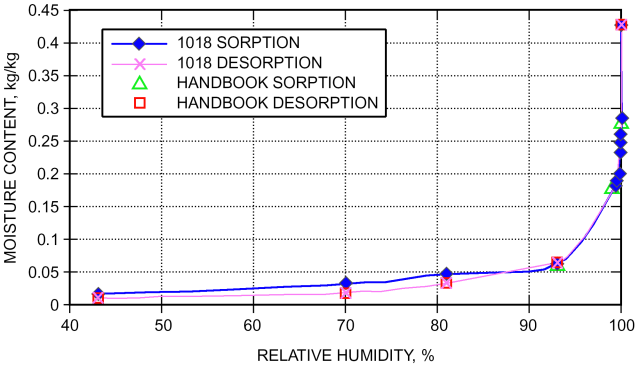

Fig. 5 Sorption/Desorption Isotherms, Cement Board

Figure 5 shows an example of a conventional sorption isotherm graph. Curves show sorption (wetting) and desorption (drying) for data in Table 7 and from Kumaran (2002). (Data from Table 7 were selectively used to provide an accurate representation of the sorption isotherm; not all data from the original source are represented.)

4.7 SOILS DATA

Apparent soil thermal conductivity is difficult to estimate and may change in the same soil at different times because of changed moisture conditions and freezing temperatures.

Figure 6 shows typical apparent soil thermal conductivity as a function of moisture content for different general types of soil. The figure is based on data presented in Salomone and Marlowe (1989) using envelopes of thermal behavior coupled with field moisture content ranges for different soil types. In Figure 6, "well graded" applies to granular soils with good representation of all particle sizes from largest to smallest. "Poorly graded" refers to granular soils with either uniform gradation, in which most particles are about the same size, or skip (or gap) gradation, in which particles of one or more intermediate sizes are not present.

Although thermal conductivity varies greatly over the complete range of possible moisture contents, this range can be narrowed if it

[a]See Chapter 25. Thermal resistance values were determined from $R = 1/C$, where $C = h_c + \varepsilon_{eff} h_r$, h_c is conduction/convection coefficient, $\varepsilon_{eff} h_r$ is radiation coefficient $\approx 0.227\varepsilon_{eff}[(t_m + 273)/100]^3$, and t_m is mean temperature of air space. Values for h_c were determined from data developed by Robinson et al. (1954). Equations (5) to (7) in Yarbrough (1983) show data in this table in analytic form. For extrapolation from this table to air spaces less than 12.5 mm (e.g., insulating window glass), assume $h_c = 21.8(1 + 0.00274t_m)/l$, where l is air space thickness in mm, and h_c is heat transfer in W/(m²·K) through air space only.

[b]Values based on data presented by Robinson et al. (1954). (Also see Chapter 4, Tables 5 and 6, and Chapter 33.) Values apply for ideal conditions (i.e., air spaces of uniform thickness bounded by plane, smooth, parallel surfaces with no air leakage to or from the space). **This table should not be used for hollow siding or profiled cladding: see Table 1.** For greater accuracy, use overall U-factors determined through guarded hot box (ASTM *Standard* C1363) testing. Thermal resistance values for multiple air spaces must be based on careful estimates of mean temperature differences for each air space.

[c]A single resistance value cannot account for multiple air spaces; each air space requires a separate resistance calculation that applies only for established boundary conditions. Resistances of horizontal spaces with heat flow downward are substantially independent of temperature difference.

[d]Interpolation is permissible for other values of mean temperature, temperature difference, and effective emittance ε_{eff}. Interpolation and moderate extrapolation for air spaces greater than 90 mm are also permissible.

[e]Effective emittance ε_{eff} of air space is given by $1/\varepsilon_{eff} = 1/\varepsilon_1 + 1/\varepsilon_2 - 1$, where ε_1 and ε_2 are emittances of surfaces of air space (see Table 2). **Also, oxidation, corrosion, and accumulation of dust and dirt can dramatically increase surface emittance. Emittance values of 0.05 should only be used where the highly reflective surface can be maintained over the service life of the assembly.**

Exterior insulated finish system (EIFS), 1 mm, 1140 kg/m^3	0

As heat flows through soil, moisture tends to move away from the heat source. This moisture migration provides initial mass transport of heat, but it also dries the soil adjacent to the heat source, thus lowering the apparent thermal conductivity in that zone of soil.

Typically, when other factors are held constant, k increases with moisture content and with dry density of a soil, but decreases with increasing organic content of a soil and for uniform gradations and rounded soil grains (because grain-to-grain contacts are reduced). The k of a frozen soil may be higher or lower than that of the same unfrozen soil (because the conductivity of ice is higher than that of water but lower than that of typical soil grains). Differences in k below moisture contents of 7 to 8% are quite small. At approximately 15% moisture content, k may vary up to 30% from unfrozen values.

When calculating annual energy use, choose values that represent typical mean site conditions. In climates where ground freezing is significant, accurate heat transfer simulations should include the

Table 4 Air Permeability of Different Materials

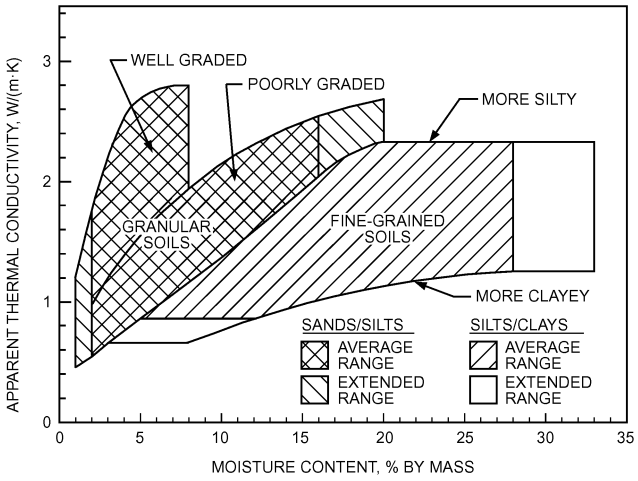

Fig. 6 Trends of Apparent Thermal Conductivity of Moist Soils

is assumed that the moisture contents of most field soils lie between the **wilting point** of the soil (i.e., the moisture content of a soil below which a plant cannot alleviate its wilting symptoms) and the **field capacity** of the soil (i.e., the moisture content of a soil that has been thoroughly wetted and then drained until the drainage rate has become negligibly small). After a prolonged dry spell, moisture is near the wilting point, and after a rainy period, soil has moisture content near its field capacity. Moisture contents at these limits have been studied by many agricultural researchers, and data for different types of soil are given by Kersten (1949) and Salomone and Marlowe (1989). Shaded areas in Figure 6 approximate (1) the full range of moisture contents for different soil types and (2) a range between average values of each limit.

Table 8 summarizes design values for thermal conductivities of the basic soil classes. Table 9 gives ranges of thermal conductivity for some basic classes of rock. The value chosen depends on whether heat transfer is calculated for minimum heat loss through the soil, as in a ground heat exchange system, or a maximum value, as in peak winter heat loss calculations for a basement. Hence, high and low values are given for each soil class.
effect of the latent heat of fusion of water. Energy released during this phase change significantly retards the progress of the frost front in moist soils.

For further information, see Chapter 17, which includes a method for estimating heat loss through foundations.

4.8 SURFACE FILM COEFFICIENTS/ RESISTANCES

As explained in Chapter 25, the overall thermal resistance of an assembly comprises its surface-to-surface thermal resistance R_s and the surface film resistances between the assembly's surfaces and the interior and exterior environment (R_i and R_o). Table 10 gives typical values for the surface film coefficients h_i and h_o and their reciprocals, the surface resistances R_i and R_o. As shown, the indoor values depend on position of the surface, direction of heat transfer, and the

Single kraft, double	0.16		1170	2400		
Polyamide film, 2 mil			62.9	1174		

Source: Lotz (1964).

[a]This table allows comparisons of materials, but when selecting vapor retarder materials, exact values for permeance or permeability should be obtained from manufacturer or from laboratory tests. Values shown indicate variations among mean values for materials that are similar but of different density, orientation, lot, or source. Values should not be used as design or specification data. Values from dry- and wet-cup methods were usually obtained from investigations using ASTM *Standards* C355 and E96; other values were obtained by two-temperature, special cell, and air velocity methods.

[b]Usually installed as vapor retarders, although sometimes used as exterior finish and elsewhere near the cold side, where special considerations are then required for warm-side barrier effectiveness.

[c]Low-permeance sheets used as vapor retarders. High permeance used elsewhere in construction.

**EIFS vapor permeance was tested with polymer cement base coat and latex acrylic finish coat of 4.4 mm thickness applied to expanded polystyrene of 34 mm thickness.

surface's long-wave emissivity. Outdoors, the values depends on air speed and the surface's long-wave emissivity. Table 10 reflects standard situations, with an assumed (approximate) interior surface temperature representative of wall or roof assemblies. For situations that deviate substantially from standard conditions, including interior surface temperatures for fenestration systems, use ASHRAE (1998)

or values from Chapter 15 to determine the surface film coefficients/resistances. Table 11 lists the standard surface film coefficient values used in European standards.

4.9 CODES AND STANDARDS

ASHRAE. 2010. Energy standard for buildings except low-rise residential buildings. ANSI/ASHRAE/IES *Standard* 90.1-2010.

ASTM. 2010. Standard terminology relating to thermal insulation. *Standard* C168-10. American Society for Testing and Materials, West Conshohocken, PA.

ASTM. 2010. Standard test method for steady-state heat flux measurements and thermal transmission properties by means of the guarded-hot-plate apparatus. *Standard* C177-10. American Society for Testing and Materials, West Conshohocken, PA.

ASTM. 2010. Standard test method for steady-state heat transfer properties of pipe insulation. *Standard* C335/C335M-10e1. American Society for Testing and Materials, West Conshohocken, PA.

ASTM. 2010. Standard test method for steady-state thermal transmission properties by means of the heat flow meter apparatus. *Standard* C518-10. American Society for Testing and Materials, West Conshohocken, PA.

ASTM. 2015. Standard practice for selection of water vapor retarders for thermal insulation. *Standard* C755-10 (R2015). American Society for Testing and Materials, West Conshohocken, PA.

ASTM. 2005. Standard classification of potential health and safety concerns associated with thermal insulation materials and accessories. *Standard* C930-05. American Society for Testing and Materials, West Conshohocken, PA.

ASTM. 2013. Standard practice for calculating thermal transmission properties under steady-state conditions. *Standard* C1045-07 (R2013). American Society for Testing and Materials, West Conshohocken, PA.

ASTM. 2011. Standard test method for thermal performance of building materials and envelope assemblies by means of a hot box apparatus. *Standard* C1363-11. American Society for Testing and Materials, West Conshohocken, PA.

ASTM. 2016. Standard specification for insulated vinyl siding. *Standard* D7793-16. American Society for Testing and Materials, West Conshohocken, PA.

ASTM. 2010. Standard test methods for water vapor transmission of materials. *Standard* E96/E96M-10. American Society for Testing and Materials, West Conshohocken, PA.

Table 8 Typical Apparent Thermal Conductivity Values for Soils, W/(m·K)

	Normal Range	Recommended Values for Design[a]	
		Low[b]	High[c]
Sands	0.6 to 2.5	0.78	2.25
Silts	0.9 to 2.5	1.64	2.25
Clays	0.9 to 1.6	1.12	1.56
Loams	0.9 to 2.5	0.95	2.25

[a]Reasonable values for use when no site- or soil-specific data are available.
[b]Moderately conservative values for minimum heat loss through soil (e.g., use in soil heat exchanger or earth-contact cooling calculations). Values are from Salomone and Marlowe (1989).
[c]Moderately conservative values for maximum heat loss through soil (e.g., use in peak winter heat loss calculations). Values are from Salomone and Marlowe (1989).

Table 9 Typical Apparent Thermal Conductivity Values for Rocks, W/(m·K)

	Normal Range
Pumice, tuff, obsidian	0.5 to 2.2
Basalt	0.5 to 2.6
Shale	0.9 to 4.0
Granite	1.7 to 4.3
Limestone, dolomite, marble	1.2 to 4.3
Quartzose sandstone	1.4 to 7.8

ASTM. 2009. Standard practices for air leakage site detection in building envelopes and air barrier systems. *Standard* E1186-03 (2009). American Society for Testing and Materials, West Conshohocken, PA.

ASTM. 2011. Standard specification for air barrier (AB) material or system for low-rise framed building walls. *Standard* E1677-11. American Society for Testing and Materials, West Conshohocken, PA.

ASTM. 2011. Standard test method for determining air leakage of air barrier assemblies. *Standard* E2357-11. American Society for Testing and Materials, West Conshohocken, PA.

CAN/ULC. 2003. Standard for determination of log-term thermal resistance of closed-cell thermal insulating foams. CAN/ULC *Standard* S770-2003. Standards Council of Canada, Ottawa, ON, and Underwriters Laboratories Canada, Toronto, ON.

VDI. 1999. Environmental meteorology—Interactions between atmosphere and surfaces—Calculation of short-wave and long-wave radiation. *Standard* 3789 Part 2. Verein Deutscher Ingenieure (Association of German Engineers), Dusseldorf.

Table 10 Surface Film Coefficients/Resistances

Position of Surface	Direction of Heat Flow	Surface Emittance, ε: Nonreflective ε = 0.90		Reflective ε = 0.20		Reflective ε = 0.05	
		h_i	R_i	h_i	R_i	h_i	R_i
Indoor							
Horizontal	Upward	9.26	0.11	5.17	0.19	4.32	0.23
Sloping at 45°	Upward	9.09	0.11	5.00	0.20	4.15	0.24
Vertical	Horizontal	8.29	0.12	4.20	0.24	3.35	0.30
Sloping at 45°	Downward	7.50	0.13	3.41	0.29	2.56	0.39
Horizontal	Downward	6.13	0.16	2.10	0.48	1.25	0.80
Outdoor (any position)		h_o	R_o				
Wind (for winter) at 6.7 m/s	Any	34.0	0.030	—	—	—	—
Wind (for summer) at 3.4 m/s	Any	22.7	0.044	—	—	—	—

Notes:
1. Surface conductance h_i and h_o measured in W/(m²·K); resistance R_i and R_o in (m²·K)/W.
2. No surface has both an air space resistance value and a surface resistance value.
3. Conductances are for surfaces of the stated emittance facing virtual blackbody surroundings at same temperature as ambient air. Values based on surface/air temperature difference of 5.6 K and surface temperatures of 21°C.
4. See Chapter 4 for more detailed information.
5. Condensate can have significant effect on surface emittance (see Table 2). Also, oxidation, corrosion, and accumulation of dust and dirt can dramatically increase surface emittance. Emittance values of 0.05 should only be used where highly reflective surface can be maintained over the service life of the assembly.

Table 11 European Surface Film Coefficients/Resistances

Position of Surface	Direction of Heat Flow	h, W/(m²·K)	R, (m²·K)/W
Indoors			
Horizontal, sloping till 45°	Upward	10	0.1
	Downward	6	0.17
Vertical, sloping beyond 45°	Any direction	7.7	0.13
Outdoors		25	0.04

CHAPTER 27

HEAT, AIR, AND MOISTURE CONTROL IN BUILDING ASSEMBLIES—EXAMPLES

HEAT TRANSFER 27.1
One-Dimensional Assembly U-Factor Calculation 27.1
Two-Dimensional Assembly U-Factor Calculation 27.3
MOISTURE TRANSPORT 27.7
Wall with Insulated Sheathing 27.7
Vapor Pressure Profile (Glaser or Dew-Point) Analysis 27.8
TRANSIENT HYGROTHERMAL MODELING 27.10
AIR MOVEMENT 27.12

THERMAL and moisture design as well as long-term performance must be considered during the planning phase of buildings. Installing appropriate insulation layers and taking appropriate air and moisture control measures can be much more economical during construction than later. Design and material selection should be based on

- Building use
- Interior and exterior climate
- Space availability
- Thermal and moisture properties of materials
- Other properties required by location of materials
- Durability of materials
- Compatibility with adjacent materials
- Performance expectations of the assembly

Designers and builders often rely on generic guidelines and past building practice as the basis for system and material selection. Although this approach may provide insight for design decisions, selections and performance requirements should be set through engineering analysis of project-specific criteria. Recent developments have increased the capabilities of available tools and methods of thermal and moisture analysis.

This chapter draws on Chapter 25's fundamental information on heat, air and moisture transport in building assemblies, as well as Chapter 26's material property data. Examples here demonstrate calculation of heat, moisture, and air transport in typical assemblies. For design guidance for common building envelope assemblies and conditions, see Chapter 45 of the 2019 *ASHRAE Handbook—HVAC Applications*.

Insulation specifically for mechanical systems is discussed in Chapter 23. For specific industrial applications of insulated assemblies, see the appropriate chapter in other ASHRAE Handbook volumes. In the 2018 *ASHRAE Handbook—Refrigeration*, for refrigerators and freezers, see Chapters 15, 16, and 17; for insulation systems for refrigerant piping, see Chapter 10; for refrigerated-facility design, see Chapters 23 and 24; for trucks, trailers, rail cars, and containers, see Chapter 25; for marine refrigeration, see Chapter 26. For environmental test facilities, see Chapter 37 in the 2002 *ASHRAE Handbook—Refrigeration*.

Engineering practice is predicated on the assumption that performance effects can be viewed in functional format, where discrete input values lead to discrete output values that may be assessed for acceptability. Heat transfer in solids lends itself to engineering analysis because material properties are relatively constant and easy to characterize, the transport equations are well established, analysis results tend toward linearity, and, for well-defined input values, output values are well defined. Airflow and moisture transport analysis, in contrast, is difficult: material properties are difficult to characterize, transport equations are not well defined, analysis results tend toward nonlinearity, and both input and output values include great uncertainty. Air movement is even more difficult to characterize than moisture transport.

Engineering makes use of the continuum in understanding from physical principles, to simple applications, to complex applications, to design guidance. Complex design applications can be handled by computers; however, this chapter begins by presenting simpler examples as a learning tool. Because complex applications are built up from simpler ones, understanding the simpler applications ensures that a critical engineering oversight of complex (computer) applications is retained. Computers have facilitated widespread use of two- and three-dimensional analysis as well as transient (time-dependent) calculations. As a consequence, steady-state calculations are less widely used. Design guidance, notably guidance regarding use of air and vapor barriers, faces changes in light of sophisticated transient calculations. ASHRAE *Standard* 160 creates a framework for using transient hygrothermal calculations in building envelope design. However, designers should recognize the limitations of these tools, as discussed in the following sections, and the need for continued advancements in the methods of analysis and understanding of heat and moisture migration in buildings.

The following definitions pertain to heat transfer properties of envelope assemblies (see Chapter 25).

Symbol	Definition
R_{System}, C_{System}	System resistance (conductance); surface-to-surface resistance (conductance) for all materials in wall, including parallel paths for framing
$R_{Assembly}$, $U_{Assembly}$	Assembly resistance (transmittance); air-to-air thermal resistance (transmittance), equal to system value plus film resistances (conductances)
U_{Whole}	Assembly thermal transmittance, including thermal bridges (i.e., $U_{Assembly}$ plus bridge conductances)

Note: For all code applications that call for U, U_{Whole} should be used.

1. HEAT TRANSFER

1.1 ONE-DIMENSIONAL ASSEMBLY U-FACTOR CALCULATION

Wall Assembly U-Factor

The assembly U-factor for a building envelope assembly determines the rate of steady-state heat conduction through the assembly. One-dimensional heat flow through building envelope assemblies is the starting point for determining whole-building heat transmittance.

Example 1. Calculate the system R-value R_{System}, assembly total resistance ($R_{Assembly}$), and $U_{Assembly}$-factor of the sandwich panel assembly shown in Figure 1; assume winter conditions when selecting values for air films from Table 3 in Chapter 26.

Solution: Determine indoor and outdoor air film resistances from Table 3 in Chapter 26, and thermal resistance of all components from Table 1 in that chapter. If any elements are described by conductivity

The preparation of this chapter is assigned to TC 4.4, Building Materials and Building Envelope Performance.

(independent of thickness) rather than thermal resistance (thickness-dependent), then calculate the resistance.

Element	R, (m²·K)/W
1. Outdoor air film	0.030
2. Vinyl siding (hollow backed)	0.107
3. Vapor-permeable felt	0.011
4. Oriented strand board (OSB), 11 mm	0.11
5. 150 mm expanded polystyrene, extruded (smooth skin)	5.28
6. 13 mm gypsum wallboard	0.079
7. Indoor air film	0.120
Total	5.70

The conductivity k of expanded polystyrene is 0.035 W/(m·K). For 150 mm thickness,

$$R_{foam} = x/k = 0.150/0.035 = 4.29 \text{ (m}^2\cdot\text{K)/W}$$

To calculate the system's R-value in the example, sum the R-values of the system components only, disregarding indoor and outdoor air films.

$$R_{System} = 0.107 + 0.011 + 0.07 + 4.29 + 0.079 = 4.56 \text{ (m}^2\cdot\text{K)/W}$$

The assembly R-value ($R_{Assembly}$) consists of the system's R-value plus the thermal resistance of the interior and exterior air films.

$$R_{Assembly} = R_o + R_{System} + R_i = 4.70 \text{ (m}^2\cdot\text{K)/W}$$

The wall's $U_{Assembly}$-factor is $1/R_{Assembly}$, or 0.21 W/(m²·K).

Roof Assembly U-Factor

Example 2. Find the U-factor of the commercial roof assembly shown in Figure 2; assume summer conditions when selecting values for air films from Table 3 in Chapter 26.

Solution: The calculation procedure is similar to that shown in Example 1. Note the U-factor of nonvertical assemblies depends on the direction of heat flow [i.e., whether the calculation is for winter (heat flow up) or summer (heat flow down)], because the resistances of indoor air films and plane air spaces in ceilings differ, based on the heat flow direction (see Table 3 in Chapter 26). The effects of mechanical fasteners are not addressed in this example.

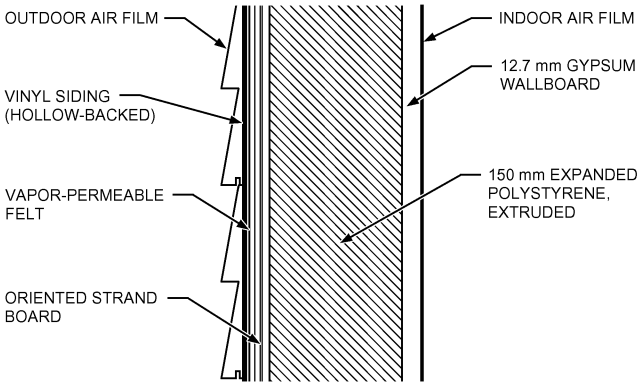

Fig. 1 Structural Insulated Panel Assembly (Example 1)

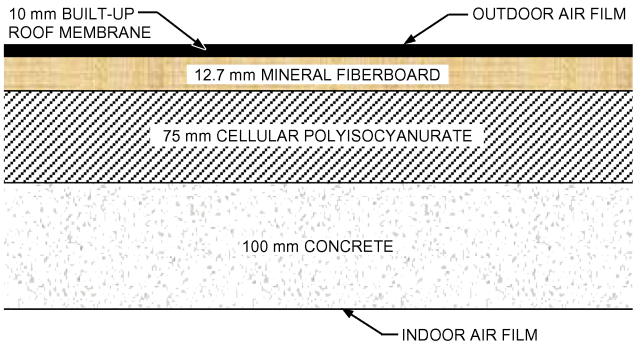

Fig. 2 Roof Assembly (Example 2)

Element	R, (m²·K)/W
1. Indoor air film	0.16
2. 100 mm concrete, 1920 kg/m³, k = 1.1	0.09
3. 75 mm cellular polyisocyanurate (gas-impermeable facers)	4.97
4. 25 mm mineral fiberboard	0.52
5. 10 mm built-up roof membrane	0.06
6. Outdoor air film	0.04
Total	5.83

Using $U_{Assembly} = 1/R_{Assembly}$, the $U_{Assembly}$-factor is 0.17 W/(m²·K).

Attics

During sunny periods, unconditioned attics may be hotter than outdoor air. Peak attic temperatures on a hot, sunny day may be 10 to 45 K above outdoor air temperature, depending on factors such as shingle color, roof framing type, air exchange rate through vents, and use of radiant barriers. Therefore, simple one-dimensional solutions cannot be offered for attics. Energy efficiency estimates can be obtained using models such as Wilkes (1991).

Basement Walls and Floors

Heat transfer through basement walls and floors to the ground depends on the following factors: (1) the difference between the air temperature in the room and that of the ground and outside air, (2) the material of the walls or floor, and (3) the thermal conductivity of surrounding earth. The latter varies with local conditions and is usually unknown. Because of the great thermal inertia of surrounding soil, ground temperature varies with depth, and there is a substantial time lag between changes in outdoor air temperatures and corresponding changes in ground temperatures. As a result, ground-coupled heat transfer is less amenable to steady-state representation than above-grade building elements. However, there are several simplified procedures for estimating ground-coupled heat transfer. These fall into two main categories: (1) those that reduce the ground heat transfer problem to a closed-form solution, and (2) those that use simple regression equations developed from statistically reduced multidimensional transient analyses.

Closed-form solutions, including Latta and Boileau's (1969) procedure discussed in Chapter 17, generally reduce the problem to one-dimensional, steady-state heat transfer. These procedures use simple, "effective" U-factors or ground temperatures or both. Methods differ in the various parameters averaged or manipulated to obtain these effective values. Closed-form solutions provide acceptable results in climates that have a single dominant season, because the dominant season persists long enough to allow a reasonable approximation of steady-state conditions at shallow depths. The large errors (percentage) that are likely during transition seasons should not seriously affect building design decisions, because these heat flows are relatively insignificant compared to those of the principal season.

The ASHRAE arc-length procedure (Latta and Boileau 1969) is a reliable method for wall heat losses in cold winter climates. Chapter 17 discusses a slab-on-grade floor model developed by one study. Although both procedures give results comparable to transient computer solutions for cold climates, their results for warmer U.S. climates differ substantially.

Research conducted by Dill et al. (1945) and Hougten et al. (1942) indicates a heat flow of approximately 6.3 W/m² through an uninsulated concrete basement floor with a temperature difference of 11 K between the basement floor and the air 150 mm above it. A U-factor of 5.7 W/(m²·K) is sometimes used for concrete basement floors on the ground. For basement walls below grade, the temperature difference for winter design conditions is greater than for the floor. Test results indicate that, at the mid-height of the below-grade

Licensed for single user. © 2021 ASHRAE, Inc.

Licensed for single user. © 2021 ASHRAE, Inc.

portion of the basement wall, the unit area heat loss is approximately twice that of the floor.

For small concrete slab floors (equal in area to a 7.5 by 7.5 m house) in contact with the ground at grade level, tests indicate that heat loss can be calculated as proportional to the length of exposed edge rather than total area. This amounts to 1.4 W per linear metre of exposed edge per degree temperature difference between indoor air and the average outdoor air temperature. This value can be reduced appreciably by installing insulation under the ground slab and along the edge between the floor and abutting walls. In most calculations, if the perimeter loss is calculated accurately, no other floor losses need to be considered. Chapters 17 and 18 contain heat transfer and load calculation guidance for floors on grade and at different depths below grade.

The second category of simplified procedures uses transient two-dimensional computer models to generate ground heat transfer data, which are then reduced to compact form by regression analysis (Mitalas 1982, 1983; Shipp 1983). These are the most accurate procedures available, but the database is very expensive to generate. In addition, these methods are limited to the range of climates and constructions specifically examined. Extrapolating beyond the outer bounds of the regression surfaces can produce significant errors.

Guide details and recommendations related to application of concepts for basements are provided in Chapter 45 of the 2019 *ASHRAE Handbook—HVAC Applications*. Detailed analysis of heat transfer through foundation insulation may also be found in the *Building Foundation Design Handbook* (Labs et al. 1988).

1.2 TWO-DIMENSIONAL ASSEMBLY U-FACTOR CALCULATION

The following examples show three methods of two-dimensional, steady-state conductive heat transfer analysis through wall assemblies. They offer approximations to overall rates of heat transfer (U-factor) when assemblies contain a layer composed of dissimilar materials. The methods are described in Chapter 25. The **parallel-path method** is used when the thermal conductivity of the dissimilar materials in the layer are rather close in value (within the same order of magnitude), as with wood-frame walls. The **isothermal-planes method** is appropriate for materials with conductivities moderately different from those of adjacent materials (e.g., masonry). The **zone method** and the **modified zone method** are appropriate for materials with a very high difference in conductivity (two orders of magnitude or more), such as with assemblies containing metal.

Two-dimensional, steady-state heat transfer analysis is often conducted using computer-based finite difference methods. If the resolution of the analysis is sufficiently fine, computer methods provide better simulations than any of the methods described here, and the results typically show better agreement with measured values.

The methods described here do not take into account heat storage in the materials, nor do they account for varying material properties (e.g., when thermal conductivity is affected by moisture content or temperature). Transient analysis is often used in such cases.

Wood-Frame Walls

The assembly R-values and U-factors of wood-frame walls can be calculated by assuming either parallel heat flow paths through areas with different thermal resistances or by assuming isothermal planes. Equation (15) in Chapter 25 provides the basis for the two methods.

The **framing factor** expresses the fraction of the total building component (wall or roof) area that is framing. The value depends on the specific type of construction, and may vary based on local construction practices, even for the same type of construction. For stud walls 400 mm on center (OC), the fraction of insulated cavity may be as low as 0.75, where the fraction of studs, plates, and sills is 0.21 and the fraction of headers is 0.04. For studs 600 mm OC, the respective values are 0.78, 0.18, and 0.04. These fractions contain an allowance for multiple studs, plates, sills, extra framing around windows, headers, and band joists. These assumed framing fractions are used in Example 3, to illustrate the importance of including the effect of framing in determining a building's overall thermal conductance. The actual framing fraction should be calculated for each specific construction.

Example 3. Calculate the $U_{Assembly}$-factor of the 38 by 90 mm stud wall shown in Figure 3. The studs are at 400 mm OC. There is 90 mm mineral fiber batt insulation (R-2.3) in the stud space. The inside finish is 13 mm gypsum wallboard, and the outside is finished with rigid foam insulating sheathing (R-0.7) and vinyl siding. The insulated cavity occupies approximately 75% of the transmission area; the studs, plates, and sills occupy 21%; and the headers occupy 4%.

Solution: If the R-values of building elements are not already specified, obtain the R-values from Tables 1 and 3 of Chapter 26. Assume $R = 7.0$ (m²·K)/W for the wood framing. Also, assume the headers are solid wood, and group them with the studs, plates, and sills.

Two simple methods may be used to determine the U-factor of wood frame walls: parallel path and isothermal planes. For highly conductive framing members such as metal studs, the modified zone method must be used.

Parallel-Path Method:

Element	*R* (Insulated Cavity), (m²·K)/W	*R* (Studs, Plates, and Headers), (m²·K)/W
1. Outdoor air film, 6.7 m/s wind	0.03	0.03
2. Vinyl siding (hollow-backed)	0.11	0.11
3. Rigid foam insulating sheathing	0.70	0.70
4. Mineral fiber batt insulation, 90 mm	2.30	—
5. Wood stud, nominal 38 by 90 mm	—	0.77
6. Gypsum wallboard, 13 mm	0.08	0.08
7. Indoor air film, still air	0.12	0.12
	$R_1 = 3.31$	$R_2 = 1.81$

Individual U-factors are reciprocals of the R-value, so $U_1 = 0.301$ and $U_2 = 0.553$ W/(m²·K). If the wood framing is accounted for using the parallel-path flow method, the wall's U-factor is determined using Equation (15) from Chapter 25. The fractional area of insulated cavity is 0.75 and the fractional area of framing members is 0.25.

$$U_{Assembly} = (0.75 \times 0.301) + (0.25 \times 0.553) = 0.36 \text{ W/(m}^2\cdot\text{K)}$$

$$R_{Assembly} = 1/U_{Assembly} = 2.78 \text{ (m}^2\cdot\text{K)/W}$$

With the isothermal-planes method, the fractional areas are applied only to the building layer that contains the studs and cavity-fill insulation. The average R-value for this layer (R_{avs}) is added to the R-values of the other components for a total R for the assembly.

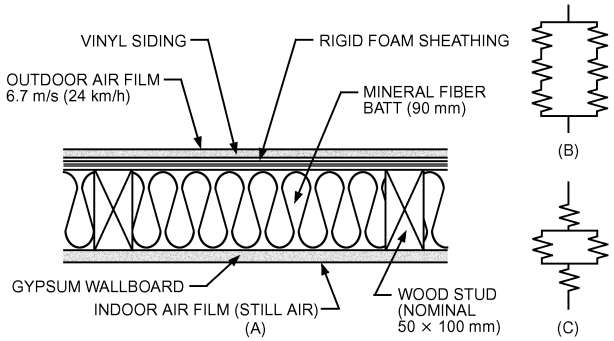

Fig. 3 (A) Wall Assembly for Example 3, with Equivalent Electrical Circuits: (B) Parallel Path and (C) Isothermal Planes

Isothermal-Planes Method:

Element	*R* (Stud Cavity Elements), (m²·K)/W	*R* (Studs, Plates, Average Cavity, and Headers), (m²·K)/W
1. Outdoor air film, 6.7 m/s wind		0.03
2. Vinyl siding (hollow-backed)		0.11
3. Rigid foam insulating sheathing		0.70
4. Mineral fiber batt insulation, 90 mm	2.30	1.54 (R_{avs})
5. Wood stud, nominal 38 by 90 mm	0.77	
6. Gypsum wallboard, 13 mm		0.08
7. Indoor air film, still air		0.12
		R_T = 2.58

The average R-value R_{avs} of the stud cavity is calculated using the fractional area of stud and insulation using Equation (15) from Chapter 25.

$$U_{avs} = 0.75(1/2.3) + 0.25(1/0.77) = 0.651$$

$$R_{avs} = 1/U_{avs} = 1.54 \text{ (m}^2\text{·K)/W}$$

If the wood framing is included using the isothermal-planes method, the U-factor of the wall is determined using Equations (10) and (11) from Chapter 25 as follows:

$$R_{Assembly} = 2.58 \text{ (m}^2\text{·K)/W}$$

$$U_{Assembly} = 1/R_{Assembly} = 0.388 \text{ W/(m}^2\text{·K)}$$

For a frame wall with a 600 mm OC stud space, the assembly R-value is 2.76 (m²·K)/W. Similar calculation procedures may be used to evaluate other wall designs, except those with thermal bridges.

Masonry Walls

The average overall R-values of masonry walls can be estimated by assuming a combination of layers in series, one or more of which provides parallel paths. This method is used because heat flows laterally through block face shells so that transverse isothermal planes result. Average total resistance $R_{Assembly}$ is the sum of the resistances of the layers between such planes, each layer calculated as shown in Example 4.

Example 4. Calculate the overall thermal resistance and average U-factor of the 194 mm thick insulated concrete block wall shown in Figure 4. The two-core block has an average web thickness of 25 mm and a face shell thickness of 32 mm. Overall block dimensions are 194 by 194 by 395 mm. Measured thermal resistances of 1700 kg/m³ concrete and 110 kg/m³ expanded perlite insulation are 0.70 and 20 (m²·K)/W, respectively. (*Note*: This type of insulation is no longer commonly used with concrete block walls. This historical example has been retained because it is a simplified case with supporting experimental data.)

Solution: The equation used to determine the overall thermal resistance of the insulated concrete block wall is derived from Equations (7) and (15) from Chapter 25 and is given below:

$$U_{Avg} = \frac{a_w}{R_w} + \frac{a_c}{R_c} \qquad R_{Avg} = \frac{1}{U_{Avg}}$$

$$R_{Assembly} = R_i + R_f + R_{avg} + R_o$$

where

$R_{T(av)}$ = overall thermal resistance based on assumption of isothermal planes
R_i = thermal resistance of inside air surface film (still air)
R_o = thermal resistance of outside air surface film (6.7 m/s wind)
R_f = total thermal resistance of face shells
R_c = thermal resistance of cores between face shells
R_w = thermal resistance of webs between face shells
a_w = fraction of total area transverse to heat flow represented by webs of blocks
a_c = fraction of total area transverse to heat flow represented by cores of blocks

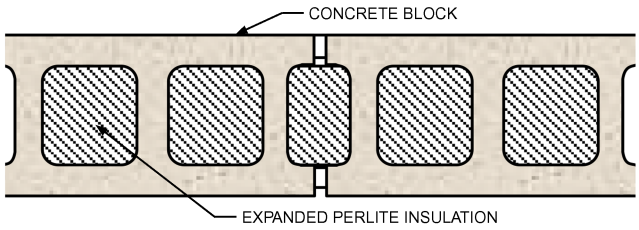

Fig. 4 Insulated Concrete Block Wall (Example 4)

From the information given and the data in Tables 1 and 3 in Chapter 26, determine the values needed to compute the overall thermal resistance.

R_i = 0.12
R_o = 0.03
R_f = 2 × 0.032 × 0.70 = 0.045
R_c = (0.194 – 2 × 0.032) × 20 = 2.60
R_w = (0.194 – 2 × 0.032) × 0.70 = 0.091
a_w = 3 × 25/395 = 0.190
a_c = 1 – 0.190 = 0.810

Using the equation given, the overall thermal resistance and average U-factor are calculated as follows:

$$U_{avs} = 0.190/0.09 + 0.810/2.60 = 2.42$$

$$R_{avs} = 1/U_{avs} = 0.413 \text{ (m}^2\text{·K)/W}$$

$$R_{Assembly} = 0.12 + 0.045 + 0.413 + 0.03 = 0.608 \text{ (m}^2\text{·K)/W}$$

$$U_{Assembly} = 1/R_{Assembly} = 1.64 \text{ W/(m}^2\text{·K)}$$

Based on guarded hot-box tests of this wall without mortar joints, Tye and Spinney (1980) measured the assembly R-value for this insulated concrete block wall as 0.551 (m²·K)/W.

Assuming parallel heat flow only, the calculated resistance is higher than that calculated on the assumption of isothermal planes. The actual resistance generally is some value between the two calculated values. In the absence of test values, examination of the construction usually reveals whether a value closer to the higher or lower calculated R-value should be used. Generally, if the construction contains a layer in which lateral conduction is high compared with transmittance through the construction, the calculation with isothermal planes should be used. If the construction has no layer of high lateral conductance, the parallel heat flow calculation should be used.

Hot-box tests of insulated and uninsulated masonry walls constructed with block of conventional configuration show that thermal resistances calculated using the isothermal planes heat flow method agree well with measured values (Shu et al. 1979; Valore 1980; Van Geem 1985). Neglecting horizontal mortar joints in conventional block can result in thermal transmittance values up to 16% lower than actual, depending on the masonry's density and thermal properties, and 1 to 6% lower, depending on the core insulation material (McIntyre 1984; Van Geem 1985). For aerated concrete block walls, other solid masonry, and multicore block walls with full mortar joints, neglecting mortar joints can cause errors in R-values up to 40% (Valore 1988). Horizontal mortar joints, usually found in concrete block wall construction, are neglected in Example 4.

Constructions Containing Metal

Curtain and metal stud-wall constructions often include metallic and other thermal bridges, which can significantly reduce the thermal resistance. However, the capacity of the adjacent facing materials to transmit heat transversely to the metal is limited, and some contact resistance between all materials in contact limits the reduction. Contact resistances in building structures are only 0.01 to 0.1 (m²·K)/W, too small to be of concern in many cases. For these

Licensed for single user. © 2021 ASHRAE, Inc.

metal stud/wall constructions, the recommended approach is the modified zone method (see Example 7) or two-dimensional analysis software such as THERM.

Thermal characteristics for panels of sandwich construction can be computed by combining the thermal resistances of the layers. R-values for assembled sections should be determined on a representative sample by using a hot-box method. If the sample is a wall section with air cavities on both sides of fibrous insulation, the sample must be of representative height because convective airflow can contribute significantly to heat flow through the test section. Computer modeling can also be useful, but all heat transfer mechanisms must be considered.

The metal studs in Example 5 are 90 mm deep and placed at 400 mm on center. The metal member is only 0.5 mm thick, but it is in contact with adjacent facings over a 32 mm wide area. The steel member is 32 mm deep, has a thermal resistance of approximately 0.0019 $(m^2 \cdot K)/W$, and is virtually isothermal.

For this insulated steel frame wall, Farouk and Larson (1983) measured an assembly R-value of 1.16 $(m^2 \cdot K)/W$. For the same assembly, the recommended modified zone method (see Example 5) gives an assembly R-value of 1.18 $(m^2 \cdot K)/W$. Two-dimensional analysis (THERM) yields U_{av} = 1.0 or R = 1.00 $(m^2 \cdot K)/W$. ASHRAE/IES *Standard* 90.1 describes how to determine the thermal resistance of wall assemblies containing metal framing by using insulation/framing adjustment factors in Table A9.2B of the standard. For 38 by 90 mm steel framing, 400 mm OC, $F_c = 0.50$. Using the correction factor method, an assembly R-value of 1.13 $(m^2 \cdot K)/W$ [0.08 + 1.94(0.50) + 0.08] is obtained for the wall described here.

Zone Method of Calculation

For structures with widely spaced metal members of substantial cross-sectional area, the isothermal planes method can give thermal resistance values that are too low. For these constructions, the **zone method** can be used. This method involves two separate computations: one for a chosen limited portion, zone A, containing the highly conductive element; the other for the remaining portion of simpler construction, zone B. The two computations are then combined using the parallel-flow method, and the average transmittance per unit overall area is calculated. The basic laws of heat transfer are applied by adding the area conductances CA of elements in parallel, and adding area resistances R/A of elements in series. The modified zone method improves on the zone method with better guidance for defining the widths of zones A and B.

Modified Zone Method for Metal Stud Walls with Insulated Cavities

The modified zone method is similar to the parallel-path and zone methods; all three are based on parallel-path calculations. Figure 5 shows the width w of the zone of thermal anomalies around a metal stud. This zone can be assumed to equal the length of the stud flange L (parallel-path method), or can be calculated as a sum of the length of stud flange and a distance double that from wall surface to metal Σd_i (zone method). In the modified zone method, the width of the zone depends on three parameters:

- Ratio between thermal resistivity of sheathing material and cavity insulation
- Size (depth) of stud
- Thickness of sheathing material

Example 5. Calculate the U-factor of the wall section shown in Figure 5 using the modified zone method.

Solution: The wall cross section is divided into two zones: the zone of thermal anomalies around the metal stud (zone W), and the cavity zone (zone *cav*). Wall material layers are grouped into exterior and interior surface sections A (sheathing, siding) and B (wallboard), and interstitial sections I and II (cavity insulation, metal stud flange).

Assuming that the wall materials in section A are thicker than those in section B, as shown, they can be described as follows:

$$\sum_{i=1}^{n} d_i \geq \sum_{j=1}^{m} d_j$$

where

n = number of material layers (of thickness d_i) between metal stud flange and wall surface for section A
m = number of material layers (of thickness d_j) for section B

Then, the width W of zone W can be estimated by

$$W = L + z_f \sum_{i=1}^{n} d_i$$

where

L = stud flange size
d_i = thickness of material layers in section A
z_f = zone factor, shown in Figure 6 (z_f = 2 for zone method)

Kosny and Christian (1995) developed the modified zone method and verified its accuracy for over 200 simulated cases of metal frame walls with insulated cavities. For all configurations considered, the discrepancy between results were within ±2%. Hot-box-measured R-values for 15 metal stud walls tested by Barbour et al. (1994) were compared with results obtained by Kosny and Christian (1995) and McGowan and Desjarlais (1997). The modified zone method was found to be the most accurate simple method for estimating the clear-wall R-value of light-gage steel stud walls with insulated cavities. However, this analysis does not apply to construction with metal sheathing. Also, ASHRAE *Standard* 90.1 may require a different method of analysis.

Step 1. Determine zone factor z_f, and the ratio of the exterior sheathing material's resistivity to the cavity material's resistivity. Resistivity r is the reciprocal of conductivity; Table 1 in Chapter 26 lists conductivities of various materials.

Element	Symbol	Value	Units
Stud spacing	s	0.406	m
Resistivity of sheathing material	r_i	34.67	(m·K)/W
Resistivity of cavity insulation	r_{ins}	23.92	(m·K)/W
Ratio r_i/r_{ins}		1.449	(no units)
Zone factor from chart	z_f	1.71	(no units)

Step 2. Calculate width W of affected zone W:

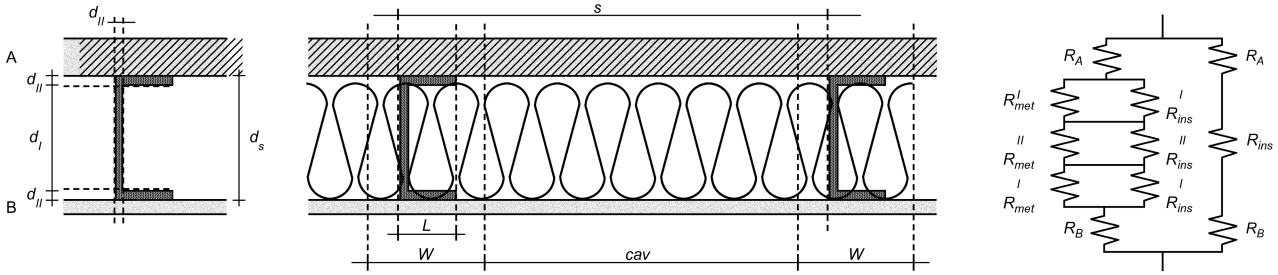

Fig. 5 Wall Section and Equivalent Electrical Circuit (Example 5)

Licensed for single user. © 2021 ASHRAE, Inc.

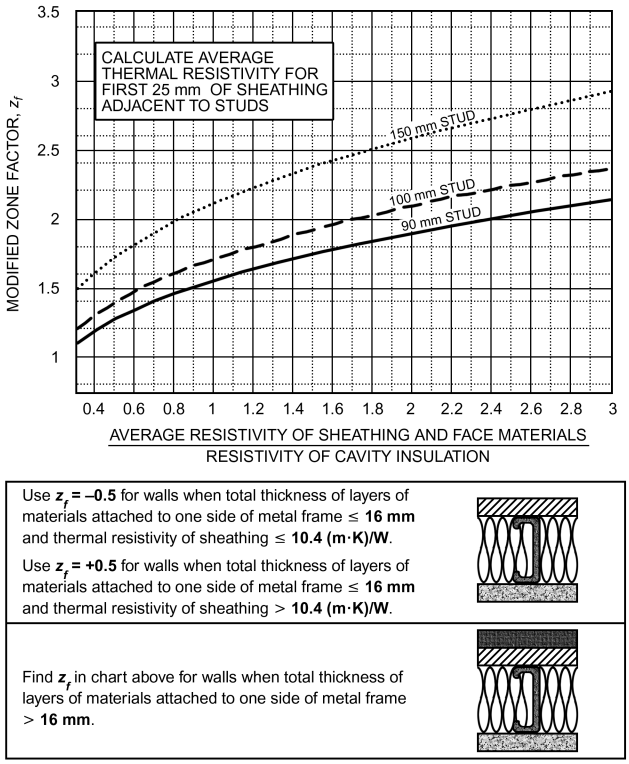

Fig. 6 Modified Zone Factor for Calculating R-Value of Metal Stud Walls with Cavity Insulation

$$W = L + z_f \sum d_i$$

Element	Symbol	Value	Units
Cavity thickness	d_s	0.089	m
Thickness of metal	d_{II}	0.0010	m
Interior dimension between flanges	d_I	0.088	m
Thickness of exterior insulating materials		0.051	m
Flange length	L	0.038	m
Affected zone thickness	W	0.125	m

Step 3. Calculate the exterior and interior thermal resistances, using conductivity or thermal resistance values from step 1.

Element	Symbol	Value	Units
Exterior materials			
Thickness of first exterior material	d_e	0.0381	m
Resistivity of first exterior material	r_e	34.7	(m·K)/W
Resistance of first material		1.32	(m²·K)/W
Resistances of other materials		0.145	
Sum of resistances of exterior materials	R_A	1.47	(m²·K)/W
Interior materials			
Thickness of interior material	d_j	0.00127	m
Resistivity of interior material	r_j	6.24	(m·K)/W
Resistance of interior material	R_B	0.043	(m²·K)/W

Step 4. Calculate the thermal resistance of the sections in zone around the metal element. The building elements in series from outside to inside are shown in Figure 7.

Element	Symbol	Value	Units
Resistivity of steel	r_{met}	0.0208	(m·K)/W
R^I_{ins}	d^I_{xri}	2.10	(m²·K)/W
R^{II}_{ins}	d^{II}_{xri}	0.024	(m²·K)/W
R^I_{met}	d^I_{xrmet}	0.00183	(m²·K)/W
R^{II}_{met}	d^{II}_{xrmet}	0.00002	(m²·K)/W

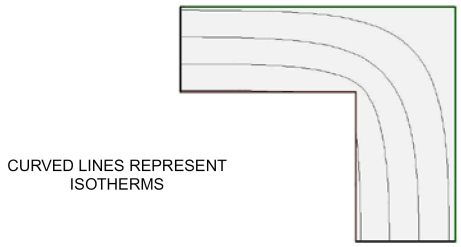

Fig. 7 Corner Composed of Homogeneous Material Showing Locations of Isotherms

The particular thermal resistances of the zone elements are then calculated.

Zone W is the zone at the web of the metal member. For width W, the thermal conductance C is calculated as the sum of the contributory areas. Because the thickness of the web of the metal member is d_I and the length along the flange section is L,

$$C_I = \frac{W - d_I}{W} C_{ins} + \frac{d_I}{W} C_{met} \quad \text{and} \quad C_{II} = \frac{W - L}{W} C_{ins} + \frac{L}{W} C_{met}$$

Using resistance rather than conductance, the contributing R-values are calculated as

$$R_I = \frac{R^I_{met} R^I_{ins} W}{d_I (R^I_{ins} - R^I_{met}) + W R^I_{met}} \quad \text{and} \quad R_{II} = \frac{R^{II}_{met} R^{II}_{ins} W}{L (R^{II}_{ins} - R^{II}_{met}) + W R^{II}_{met}}$$

At the cavity, the sum of the series R-values is

$$\sum R_{cav} = R_A + R_B + R^I_{ins} + 2R^{II}_{ins}$$

In zone W, the sum of the R-values is

$$\sum R_W = R_A + R_B + R_I + 2R_{II}$$

The total conductivity across the length s is proportional to the contributing lengths of zone W and the cavity:

$$C_{tot} = \frac{W}{s} C_W + \frac{cav}{s} C_{cav}$$

or

$$R_{tot} = \frac{\sum R_W \sum R_{cav} s}{W\left(\sum R_{cav} - \sum R_W\right) + s \sum R_W}$$

Element	Symbol	Value	Units
Resistance at web	R_I	0.203	(m²·K)/W
Resistance at flange	R_{II}	0.00007	(m²·K)/W
Sum of resistances at cavity	ΣR_{cav}	3.66	(m²·K)/W
Sum of resistances at zone W	ΣR_W	1.713	(m²·K)/W
Assembly R	$R_{Assembly}$	2.71	(m²·K)/W
Assembly U	$U_{Assembly}$	0.369	W/(m²·K)

In this example, the calculated total R-value for the wall is 2.71 (m²·K)/W, and the wall's U-factor is 0.369 W/(m²·K).

Complex Assemblies

Building enclosure geometry of two- and three-dimensional assemblies may be complex, including corners, terminations of materials, and junctures of different materials. Such assemblies cannot be analyzed effectively with explicit calculations; rather, they require iterative calculations using computers. These calculations have been made for a number of common assemblies (Hershfield 2011), and the results can be applied within a simpler estimation method, as shown in Example 6.

Buildings with thermal mass or other forms of thermal storage require dynamic models to evaluate their performance in the environmental climate of interest.

Licensed for single user. © 2021 ASHRAE, Inc.

Figure 7 shows a corner composed of homogeneous material. Surface temperatures can be estimated from the intersections of isotherms and the surface. If, in this figure, the interior were warm with respect to outside, then the line at the corner would be colder than the remainder of the interior surface. This effect may be exacerbated by the air film at the corner, which has a greater effective thickness than on the plane of the wall, and therefore offers greater thermal resistance, further lowering the corner temperature.

Figure 8 shows an insulating material applied to a conductive material. Insulation is placed at the inside, during a period of cold outdoor temperatures. A computer program may be used to trace the isotherms. The interior isotherm is cut where the insulating material is interrupted, indicating lowered temperature at that location (point A). In fact, the temperature at the edge of the interrupted insulation is even lower than that at the surface of the uninsulated wall. Interruptions in insulation can lead to thermal bridges. For this reason, insulating conductive assemblies such as masonry or concrete is often more successful when applied to the outside rather than to the inside of the building.

Example 6. Comparing Linear Transmittance Method to Area-Weighted Method for Brick Veneer Shelf Angle Anomaly.

Calculate the overall U-value of the steel-stud brick veneer assembly with a slab and shelf angle with exterior insulation R-15 (2.6 RSI) and interior stud cavity insulation R-12 (2.1 RSI) (see Figure 9), using the following information and method:

Gross wall height = 2.7 m

Gross wall length = 15.2 m

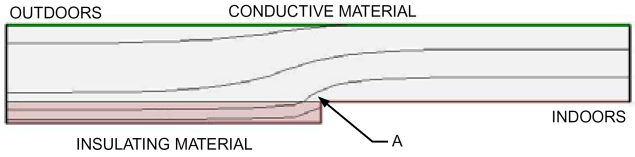

Fig. 8 Insulating Material Installed on Conductive Material, Showing Temperature Anomaly (Point A) at Insulation Edge

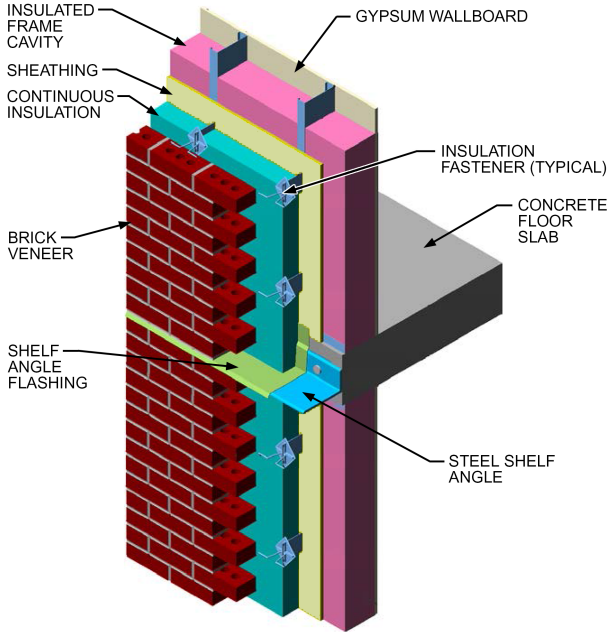

Fig. 9 Brick Veneer Shelf for Example 6

Gross wall area = 41.0 m

Area-Weighted Method. The thermal transmittance U_b for the area around the shelf angle is 1.162 W/(m^2·K) for the effective lengths L_1 = 205 mm, L_2 = 619 mm, and U_o = 0.287 W/(m^2·K). [Area thermal transmittance depends on the definition of the effective lengths (Hershfield 2011). This calculation is not shown here.]

Calculate area for the thermal anomaly and area for the clear field:

A_b =0.619 m × 15.2 m = 9.4 m^2 A_o = 41.0 – 9.4 = 31.6 m^2

Calculate the overall U-value:

$$U = \frac{(U_b A_b + U_o A_o)}{A_{total}} = \frac{(1.162 \times 9.4 + 0.287 \times 31.6)}{41} = 0.49 \text{ W/m}^2\text{·K}$$

Linear Transmittance Method. From Appendix F of RP-1365, for this brick veneer assembly, U_o = 0.287 W/(m^2·K) and the linear transmittance Ψ of a slab with a shelf angle for this assembly is 0.544 W/(m·K).

Calculate the overall U-value

$$\frac{\Psi L}{A_{total}} \quad U = \frac{\Psi L}{A_{total}} + U_o = 0.544 \times \frac{15.2}{41} + 0.29 = 0.49 \text{ W/(m}^2\text{·K)}$$

This example illustrates the simplicity of the linear transmittance method compared to the area-weighted method for thermal anomalies in opaque building envelope assemblies. The amount of information that must be provided is reduced and the calculation is simpler. The weighted average method is further complicated for a whole-building elevation when accounting for 3D intersections. Some [e.g., Kemp (1997)] suggest that the overlapping effects be combined using mitered corners.

Windows and Doors

Table 4 of Chapter 15 lists U-factors for various fenestration products. For heat transmission coefficients for wood and steel doors, see Table 6 in Chapter 15. All U-factors are approximate, because a significant portion of the resistance of a window or door is contained in the air film resistances, and some parameters that may have important effects are not considered. For example, the listed U-factors assume the surface temperatures of surrounding bodies are equal to the ambient air temperature. However, the indoor surface of a window or door in an actual installation may be exposed to nearby radiating surfaces, such as radiant heating panels, or opposite walls with much higher or lower temperatures than the indoor air. Air movement across the surface of a window or door, such as that caused by nearby heating and cooling outlet grilles or by wind outdoors, increases the U-factor.

2. MOISTURE TRANSPORT

The following examples build on the previous sections by discussing methods that combine heat and moisture transport analysis. The theory of hygrothermal analysis is described in Chapter 25. The methods include fundamental calculations that can be performed by hand as well as more advanced transient calculations that require computer modeling. A few simplified examples are presented here to aid in understanding these multimode, dynamic transport cases. These examples are simplified so that they can be explicitly calculated by assuming steady-state conditions, thus neglecting all storage phenomena. For other examples of explicit methods, see the Bibliography.

2.1 WALL WITH INSULATED SHEATHING

For an initial assessment of the impact of including any materials with low water vapor permeability in a building assembly, estimate the condensation resistance using a simplified moisture analysis. This simplified analysis assumes that interior surfaces may have little or no resistance to air or vapor flow, assumes steady-state conditions, and neglects the effect of radiative heat transfer on the

Licensed for single user. © 2021 ASHRAE, Inc.

exposed surfaces. The section on Surface Condensation in Chapter 25 describes how to determine the risk of condensation on low-permeability surfaces.

Example 7. For the assembly shown in Figure 3 (but assume the wall has a thicker layer of mineral wool insulation, per following table), determine the range of indoor relative humidity for which condensation does not occur on the inside of the insulating sheathing. Assume a design outdoor temperature of –1°C, and indoor temperature of 21°C. Assume that the cavity air is at the same vapor pressure as the indoor air, which can occur with openings through the wallboard. Ignore radiant effects on the wall exterior. Assume the rigid insulation is vapor impermeable, and interior materials have little resistance to air or vapor flow.

Air Film or Material	Thermal Resistance, $(m^2 \cdot K)/W$
1. Indoor air film coefficient	0.12
2. Gypsum wallboard	0.08
3. Mineral fiber insulation	3.34
4. 25 mm extruded polystyrene	0.88
5. OSB sheathing, 13 mm	0.12
6. Vinyl siding (hollow backed)	0.107
7. Exterior air film coefficient	0.03
Assembly R-value	4.68

Solution: The temperature difference is 22 K. The sum of the R-values from the foam/mineral fiber interface inward is 3.54 $(m^2 \cdot K)/W$. The sum of the R-values from that interface outward is 1.14 $(m^2 \cdot K)/W$. The temperature difference ratio [Equation (14), Chapter 25] is 1.14/4.68, or –0.24. The interface temperature is 4.3°C. The saturation vapor pressure of indoor air is 2476 Pa, and the saturation vapor pressure at the interface is 831 Pa (see Chapter 1). The upper bound for indoor relative humidity is therefore 831/2476, or 34% rh. (Another way to approach this problem would be to assume a given relative humidity within the indoor space and determine the range of outdoor temperatures for which condensation would not occur at this location.)

Many factors influence the likelihood (or not) of damage in an assembly such as this with exterior rigid insulation. Solar effects generally ensure a period of high temperatures that allows drying, so a design based on this result alone may be overly conservative. On the other hand, cold sky temperatures may increase heat loss from the assembly, which lowers the surface temperature below ambient, so a design based on this result alone may be subject to moisture damage. Even when indoor humidity is high enough that condensation at the interface is indicated, the rate of water formation may be slowed by airtightness at the wallboard and by vapor diffusion protection. In light of these dynamic effects, the analyst must consider the number of hours at which condensation could occur without damaging the assembly. The varying nature of the boundary conditions, as well as the storage capability of the assembly materials, lead to the need for more comprehensive dynamic evaluations (ASHRAE *Standard* 160).

2.2 VAPOR PRESSURE PROFILE (GLASER OR DEW-POINT) ANALYSIS

The historical steady-state one-dimension tool for evaluating moisture accumulation and drying within exterior envelopes (walls, roofs, and ceilings) is the dew-point or Glaser method. With the increasing prominence of transient modeling tools, much more accurate estimates of temperature and humidity can be achieved than were possible using steady-state analysis. Users should recognize the limitations of the steady-state approach, which include the following:

- Condensation is a phase change from vapor to liquid. As long as relative humidity in the pores of hygroscopic, capillary-porous building materials stays below 100%, vapor does not condense but is adsorbed as hygroscopic moisture or absorbed as liquid. Only once moisture content at the surface touches the capillary maximum will vapor condense on that surface. The dew-point method results have often been interpreted to indicate condensation, when, in fact, increases in moisture content were through sorption or absorption, not visible condensation at the surface.
- Heat and moisture storage effects are not included in a dew-point analysis. Experience shows they play a significant role in heat and moisture performance of assemblies. To account for storage, it is recommended to use average values (e.g., monthly average temperature) rather than more extreme design temperatures.
- Diffusion is the only moisture transport mechanism considered. Airflow, capillary transport, rain wetting, initial conditions, latent effects, solar effects, and ventilation cannot or only approximately can be included in the method. They may have a dominant effect on building assembly performance.
- The dew-point method allows calculation of a rate of moisture accumulation or rate of drying from a critical location within the assembly. However, the method does not allow estimating damage associated with any rate of accumulation or drying.

The method is presented here for reasons of historical continuity, and because it serves as an illustration of the principles of heat conduction and vapor diffusion. However, the dew-point method is not recommended as a sole basis for hygrothermal design of building envelope assemblies. ASHRAE *Standard* 160 is recommended to assist in hygrothermal analysis for design purposes.

Winter Wall Wetting Examples

Example 8. For a wood-framed wall, assume monthly mean conditions of 21°C, 40% rh indoors and –6.6°C, 50% rh outdoors. Indoor and outdoor vapor pressures are 995 and 175 Pa, respectively.

Solution:

Step 1. List the components in the building assembly, with their R-values and permeances.

Air Film or Material	Thermal Resistance, $(m^2 \cdot K)/W$	Proportional Temperature Drop	Vapor Permeance, $ng/(s \cdot m^2 \cdot Pa)$	Vapor Diffusion Resistance, $(Pa \cdot s \cdot m^2)/ng$	Proportional Vapor Pressure Drop
1 Surface film coefficient	0.12	0.050	9200	0.000109	0.003
2 Gypsum board, painted, cracked joints	0.08	0.033	290	0.00345	0.088
3 Insulation, mineral fiber	1.90	0.785	1700.0	0.00059	0.015
4 Plywood sheathing	0.11	0.045	29	0.03448	0.881
5 Wood siding	0.18	0.074	2010	0.00050	0.013
6 Surface film coefficient	0.03	0.012	57000	0.00002	0.000
Total	2.42	1.000		0.03914	1.000

Step 2. List the indoor and outdoor temperature and relative humidity. Vapor pressure at indoor and outdoor locations is determined by multiplying the saturation vapor pressure at that temperature by the relative humidity.

Step 3. Calculate the proportional temperature drop across each layer. The temperature drop is proportional to the R-value:

$$\frac{\Delta t_{layer}}{t_i - t_o} = \frac{R_{layer}}{R_T}$$

The table in step 1 lists the resulting proportional temperature drops. Calculate the proportional water vapor pressure drops across each layer. These are calculated the same way as the proportional temperature drops in step 1:

Licensed for single user. © 2021 ASHRAE, Inc.

$$\frac{\Delta p_{layer}}{p_i - p_o} = \frac{Z_{layer}}{Z_T}$$

where

Z_T = total water vapor diffusion resistance of wall (sum of diffusion resistances of all layers), (Pa·s·m²)/ng
p = partial water vapor pressure, Pa

Boundary or Interface Between Materials	Temperature, °C	Saturation Vapor Pressure, Pa	Rel. Hum., %	Initial Vapor Pressure, Pa	Corrected Vapor Pressure, Pa
Indoor air	21	2488	40	995	995
5-6 interface	19.6	2286		993	760
4-5 interface	18.7	2161		921	756
3-4 interface	–2.9	478		908	478
2-3 interface	–4.2	430		186	430
1-2 interface	–6.3	361		175	183
Outdoor air	–6.6	350	50	175	175
Difference	27.6		Difference	820	

Step 4. Determine the temperature at each interface, using the temperature difference from indoors to outdoors, and the proportional temperature drop. Find the saturation water vapor pressure corresponding to the interface temperatures from step 1. These values can be found in Table 2 in Chapter 1.

Step 5. From step 1, the total water vapor diffusion resistance of the wall without the vapor retarder is

$$Z_{wall} = 1/9200 + 1/290 + 1/1700 + 1/29 + 1/2010 + 1/57\,000 = 0.04 \text{ (Pa·s·m}^2\text{)/ng}$$

The partial water vapor pressure drop across the whole wall is calculated from the indoor and outdoor saturation water vapor pressures and relative humidities (see the table in step 3).

$$p_{wall} = p_i - p_o = (40/100)2488 - (50/100)350 = 820 \text{ Pa}$$

Step 6. Figure 10 shows the calculated saturation and partial water vapor pressures. Comparison reveals that the calculated partial water vapor pressure on the interior surface of the sheathing is well above saturation. This indicates incipient accumulation of water (condensation or sorption), probably on the surface of the sheathing, not within the insulation. If the accumulation rate is of interest, two additional steps are necessary.

Step 7. The calculated water vapor pressure exceeds the saturation water vapor pressure by the greatest amount at the back side of the sheathing (Figure 12). Therefore, this is the most likely location for accumulation. Under conditions of phase change (condensation or sorption), the water vapor pressure should equal the saturation water vapor pressure at that interface (see the corrected vapor pressure column in step 3).

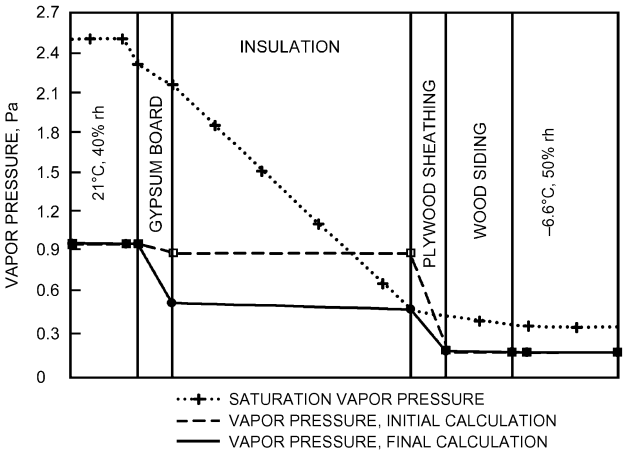

Fig. 10 Dew-Point Calculation in Wood-Framed Wall (Example 8)

Step 8. The change of water vapor pressure on the OSB sheathing alters all other partial water vapor pressures as well as water vapor flux through the wall. Calculating partial water vapor pressures is similar to the calculation in step 3, but the wall is now divided in two parts: one on the interior of the condensation interface (i.e., gypsum board and insulation) and the other on the exterior (OSB sheathing and wood siding). Water vapor pressure drop over the first (interior) part of the wall is

$$\Delta p_1 = 995 - 478 = 517 \text{ Pa}$$

and over the second (exterior) part is

$$\Delta p_2 = 478 - 175 = 303 \text{ Pa}$$

The diffusion resistances of both parts of the wall are

$$Z_1 = 1/9200 + 1/290 + 1/1700 = 0.004 \text{ (Pa·s·m}^2\text{)/ng}$$

$$Z_2 = 1/29 + 1/2010 + 1/57\,000 = 0.035 \text{ (Pa·s·m}^2\text{)/ng}$$

The water vapor pressure drops across each material can be calculated from the part between the inside and sheathing

$$\frac{\Delta p_{layer}}{p_i - p'_{sheathing}} = \frac{Z_{layer}}{Z_i^{sheathing}}$$

and the part between the sheathing and outside

$$\frac{\Delta p_{layer}}{p'_{sheathing} - p_o} = \frac{Z_{layer}}{Z^o_{sheathing}}$$

	Z_{tot}, (Pa·s·m²)/ng	Vapor Pressure Difference, Pa	Vapor Flow, ng/(s·m²)
Indoor air to critical interface	0.004	517	124 746
Critical interface to outdoor air	0.035	303	8 661

As shown in Figure 10, final calculations of water vapor pressure no longer exceed saturation, which means that the condensation plane was chosen correctly. However, vapor flux is no longer the same throughout the wall. The flux from inside increases; to the outside it decreases. The difference between both is the rate of moisture accumulation by interstitial condensation at the back side of the sheathing:

$$m_c = \frac{p_i - p'_{sheathing}}{Z_i^{sheathing}} - \frac{p'_{sheathing} - p_o}{Z^o_{sheathing}}$$

In this case m_c = 116 000 ng/(s·m²). Assume the12 mm OSB sheathing (density of 500 kg/m³) begins with moisture content of 10%. The mass of dry OSB at that thickness is 6.5 kg/m², so the mass of water is 0.65 kg. If these conditions persist for 30 days (720 h), then the amount of accumulated water is 0.30 kg. This raises the moisture content of the wood to 12.5%. It is evident that wetting by diffusion is very slow.

The Glaser method should not be used to show simply that calculated vapor pressure at one location exceeds saturation vapor pressure at that location. If that condition is detected, then the rate of accumulation must be calculated and the results compared to the affected material's estimated storage potential. Unfortunately, guidance on interpretation of accumulated water with the Glaser method is not available. Considerations of moisture storage potential in building materials can be addressed only with transient modeling, not with steady-state methods.

Example 9. A wood-framed construction has a wet layer inside. The wall layers include a 0.2 mm polyethylene membrane between insulation and gypsum board, and an exterior insulation and finish system (EIFS) with 40 mm of expanded polystyrene as substrate and a spun-glass reinforced stucco finish. If the OSB sheathing became soaked because of rain infiltration at the windows, how long before the OSB reaches hygroscopic equilibrium after leaks are sealed? Solve for two monthly mean conditions: winter, with 21°C, 40% rh indoors and –6.6°C, 50%

Licensed for single user. © 2021 ASHRAE, Inc.

rh outdoors; and summer, with 25°C, 70% rh indoors and 23°C, 70% rh outdoors.

Solution:

Step 1. List the components in the building assembly, with their R-values and permeances.

Air Film or Material	Thermal Resistance R, $(m^2 \cdot K)/W$	Proportional Temperature Drop	Vapor Permeance, ng/(Pa·s·m²)	Vapor Diffusion Resistance, (Pa·s·m²)/ng	Proportional Vapor Pressure Drop
1. Air film coefficient	0.12	0.038	9200	0.0001	0.000
2. Gypsum board, painted	0.079	0.025	290	0.003	0.001
3. Polyethylene foil	0.0	0.000	0.435	2.299	0.975
4. Insulation, mineral fiber	1.9	0.595	1700	0.001	0.000
5. OSB sheathing	0.055	0.017	29	0.034	0.015
6. EPS	1	0.313	72.5	0.014	0.006
7. EIFS stucco lamina and finish	0.01	0.003	185	0.005	0.002
8. Air film coefficient	0.03	0.009	57 000	0.00002	0.000
Total	3.19	1.000		2.36	1.000

Step 2. List the indoor and outdoor temperature and relative humidity. As in Example 8, indoor and outdoor vapor pressure is determined by multiplying the saturation vapor pressure at that temperature by the relative humidity.

Winter conditions:

	Temperature, °C	Saturated Vapor Pressure, Pa	Relative Humidity, %	Vapor Pressure, Pa
Indoors	21	2488	40	995
1 and 2	20.0	2334		995
2 and 3	19.3	2237		995
3 and 4	19.3	2237		751
4 and 5	2.9	751		**751**
5 and 6	2.4	726		**726**
6 and 7	–6.3	361		330
7 and 8	–6.3	358		176
Outdoors	–6.6	350	50	175
Difference	27.6			

Summer conditions:

	Temperature, °C	Saturated Vapor Pressure, Pa	Relative Humidity, %	Vapor Pressure, Pa
Indoors	25	3169	70	2219
1 and 2	24.9	3155		2219
2 and 3	24.9	3146		2220
3 and 4	24.9	3146		2929
4 and 5	23.7	2929		**2929**
5 and 6	23.7	2923		**2923**
6 and 7	23.0	2815		2237
7 and 8	23.0	2814		1968
Outdoors	23	2811	70	1967
Difference	2.0			

Step 3. Indoor and outdoor vapor pressures are calculated from the given conditions of temperature and relative humidity. The vapor pressure at each side of the OSB sheathing is assigned the value of the saturation vapor pressure at that temperature (see bold values in the summer and winter condition tables).

Step 4. Calculate the total vapor resistance on either side of the critical OSB layer. Between inside and sheathing,

$$\frac{\Delta p_{layer}}{p_i - p'_{sheathing}} = \frac{Z_{layer}}{Z_i^{sheathing}}$$

Between sheathing and outside,

$$\frac{\Delta p_{layer}}{p'_{sheathing} - p_o} = \frac{Z_{layer}}{Z_{sheathing}^{o}}$$

From the summer and winter condition tables, the diffusion resistances of both parts of the wall are

$$Z_1 = 0.0001 + 0.003 + 2.299 + 0.001 = 2.303 \text{ (Pa·s·m}^2\text{)/ng}$$

$$Z_2 = 0.014 + 0.005 + 0.00002 = 0.019 \text{ (Pa·s·m}^2\text{)/ng}$$

Step 5. Calculate the vapor pressure difference on either side of the critical OSB layer (the last column in the summer and winter condition tables). From the vapor resistance on each side and the vapor pressure difference on each side, vapor flow in each direction can be calculated.

Winter

$$m_{shething,\,i} = \frac{p_i - p'_{sheathing}}{Z^i_{sheathing}} = 106 \text{ ng/(s·m}^2\text{)} = 106 \text{ ng/(s·m}^2\text{)}$$

$$m_{shething,\,o} = \frac{p'_{sheathing} - p_o}{Z_o^{sheathing}} = 28\,659 \text{ ng/(s·m}^2\text{)}$$

	Z_{tot}, (Pa·s·m²)/ng	Vapor Pressure Difference, Pa	Vapor Flow, ng/(s·m²)
Indoor air to critical interface	2.303	244.4	106
Critical interface to outdoor air	0.019	550.7	28 659
		Net drying, ng/s	28 553

Summer

$$m_{shething,\,i} = \frac{p_i - p'_{sheathing}}{Z^i_{sheathing}} = -309 \text{ ng/(s·m}^2\text{)}$$

$$m_{shething,\,o} = \frac{p'_{sheathing} - p_o}{Z_o^{sheathing}} = 49\,744 \text{ ng/(s·m}^2\text{)}$$

	Z_{tot}, (Pa·s·m²)/ng	Vapor Pressure Difference, Pa	Vapor Flow, ng/(s·m²)
Indoor air to critical interface	2.303	–710.8	–309
Critical interface to outdoor air	0.019	955.9	49 744
		Net drying, ng/s	50 052

Drying consequently amounts to 74 g/m² per month in winter and 130 g/m² per month in summer. OSB soaked with water can have excess moisture content of up to 4.8 kg/m². Drying only by one-dimensional diffusion would appear to take several years at this rate. Radiation, air movement, and two- and three-dimensional effects can change the rate of drying.

Figures 11 and 12 show the calculated water vapor pressure in winter and summer. The OSB is at water vapor saturation pressure; saturation is not reached at any other interface.

3. TRANSIENT HYGROTHERMAL MODELING

Fundamentals of hygrothermal modeling tools, including modeling criteria and method of reporting, are discussed in Chapter 25. Although this chapter does not provide a complete example, it introduces input data commonly required by these programs and discusses considerations for analyzing output when using these tools.

Licensed for single user. © 2021 ASHRAE, Inc.

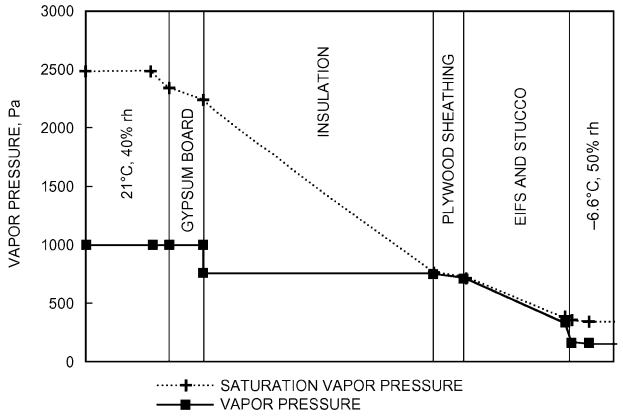

Fig. 11 Drying Wet Sheathing, Winter (Example 9)

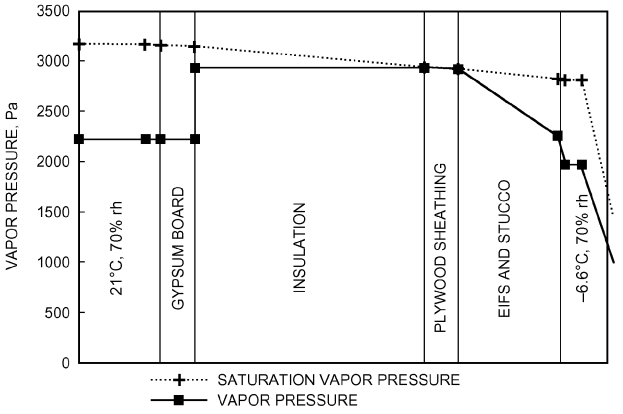

Fig. 12 Drying Wet Sheathing, Summer (Example 9)

For many applications and for design guide development, actual behavior of an assembly under transient climatic conditions may be simulated to account for short-term processes such as driving rain absorption, summer condensation, and phase changes. Computer simulations allow designers to model these conditions over time. It is important, however, to understand the model's application limits.

Applying one of these models requires at least the following information: exterior climate conditions, indoor temperature and humidity, and building assembly materials and sizes. Many programs include a material property database and exterior climate and indoor condition data, allowing simple modeling to be performed without customization. However, using generic material property and weather data may not accurately recreate actual target conditions.

Features of a complete moisture analysis model include

- Transient heat, air, and moisture transport formulation, incorporating the physics of
  - Airflow
  - Water vapor transport by advection (combination of water vapor diffusion and air-driven vapor flow)
  - Liquid transport by capillary action, gravity, and pressure differences
  - Heat flow by apparent conduction, convection, and radiation
  - Heat and moisture storage/capacity of materials
  - Condensation and evaporation processes with linked latent-to-sensible heat transformation
  - Freezing and thawing processes with linked latent-to-sensible heat transformation and based on laws of conservation of heat, mass, and momentum
- Material properties as functions of moisture content, relative humidity, and temperature, such as
  - Density
  - Air properties: permeability and permeance
  - Thermal properties: specific heat capacity, apparent thermal conductivity, Nusselt numbers, and long-wave emittance (for cavities and air spaces)
  - Moisture properties: porosity, sorption curve, water retention curve, vapor permeability, water permeability, or liquid diffusivity
- Boundary conditions (generally on an hourly basis)
  - Outside temperature and relative humidity
  - Incident short-wave solar and long-wave sky radiation (depending on inclination and orientation)
  - Wind speed, orientation, and pressures
  - Wind-driven rain at exterior surfaces (depending on location and aerodynamics)
  - Interior temperature, air pressure excess, relative humidity (or interior moisture sources and ventilation flows), and air stratification
  - Surface conditions
  - Heat transfer film coefficients (combined convection and radiation, separate for convection and radiation)
  - Mass transfer film coefficients
  - Short-wave absorptance of exterior surfaces
  - Long-wave emittance of exterior surfaces
  - Contact conditions between layers and materials. Interfaces may be bridgeable for vapor diffusion, airflow, and gravity or pressure liquid flow only. They may be ideally capillary, introduce additional capillary resistance, or behave as real contact.

Not all these features are required for every analysis, and some applications may need additional information (e.g., moisture flow through unintentional cracks and intentional openings, rain penetration through veneer walls and exterior cladding). To model these phenomena accurately, experiments may be needed to define systems and subsystems in field situation, because only then are all exterior loads and influences captured.

It is important to recognize that simulation results are based on input data. Therefore, the more accurate the input data used, the closer the results will match real-world conditions. Exterior weather conditions, material properties, and interior operating conditions all vary widely, so it is important to get the best data available on materials being modeled. For most users, this is a difficult task. Many product manufacturers do not provide the material property data needed for the simulations. Developing weather data for a particular site is also beyond the expertise of many.

Combined heat, air, and moisture models also have limitations. Users should be aware which transport phenomena and types of boundary conditions are included and which are not. For instance, some models cannot handle air transport or rain wetting of the exterior. Even an apparently simple problem, such as predicting rain leakage through a brick veneer, is beyond existing tools' capabilities. In such cases, simple qualitative schemes and field tests still are the way to proceed. In addition, results also tend to be very sensitive to the choice of indoor and outdoor conditions. Usually, exact conditions are not known.

Outputs from these programs typically include the moisture content of materials as well as relative humidity within the assembly. Interpretation of results is not easy: accurate data on moisture and temperature conditions that materials can tolerate are often not available. Although moisture accumulation may result in indoor air quality issues or material degradation, the effect of moisture accumulation in building assemblies depends on many factors, including choice of construction materials, and varies by building, making interpretation of results even more difficult.

4. AIR MOVEMENT

Moisture movement through building envelope assemblies is more strongly affected by air movement than by diffusion. To minimize moisture penetration by air leakages, the building envelope should be as airtight as possible. The airflow retarder must also be sufficiently strong and well supported to resist wind loads.

In older residential buildings, air leakage provided sufficient ventilation and rarely led to interstitial condensation. However, in airtight buildings, mechanical ventilation is needed to ensure acceptable air quality and prevent moisture and health problems caused by excessive indoor humidity. Ventilation of the wall assembly and/or drainage must go to the outside of the airtight layer of construction, or it will increase building air leakage. To avoid moisture problems at the airtight layer, either the layer temperature must be kept above the dew point by locating it on the warm side of the insulation, or the layer permeance must allow vapor transmission.

As described in detail in the section on Leakage Distribution in Chapter 16, air leakage through building envelopes is not confined to doors and windows. Although 6 to 22% of air leakage occurs there, 18 to 50% typically takes place through walls, and 3 to 30% through the ceiling. Leakage often occurs between sill plate and foundation, through interior walls, electrical outlets, plumbing penetrations, and cracks at top and bottom of exterior walls.

Not all cracks and openings can be sealed in existing buildings, nor can absolutely tight construction be achieved in new buildings. Provide as tight an enclosure as possible to reduce leakage, minimize potential condensation within the envelope, and reduce energy loss. However, the project team must also recognize the impact of airtightness.

Moisture accumulation in building envelopes can also be minimized by controlling the dominant direction of airflow by operating the building at a small negative or positive air pressure, depending on climate. In cooling climates, pressure should be positive to keep out humid outside air. In heating climates, pressure should be neither strongly negative, which could risk drawing soil gas or combustion products indoors and affect occupant comfort, nor strongly positive, which could risk driving moisture into building envelope cavities.

Equivalent Permeance

Dew-point analysis allows simple estimation of the effect of wall and roof cavity ventilation on heat and vapor transport by using parallel thermal and vapor diffusion resistances (TenWolde and Carll 1992; Trethowen 1979). These parallel resistances account for heat and vapor that bypass exterior material layers with ventilation air from outside. Equivalent thermal and water vapor diffusion resistances are approximated from the following equations:

$$R_{par} = \frac{1}{m_a c}$$

$$Z_{par} = \frac{1}{m_a \xi}$$

where

R_{par} = parallel equivalent thermal resistance, $(m^2 \cdot K)/W$
Z_{par} = parallel equivalent water vapor diffusion vapor flow resistance, $(Pa \cdot s \cdot m^2)/ng$
m_a = ventilation flux, $kg/(m^2 \cdot s)$
ξ = $0.62/P_a$, where P_a is atmospheric pressure, Pa

Solid Fuels 28.10
Combustion Calculations 28.11
Efficiency Calculations 28.15
Combustion Considerations 28.16

1. PRINCIPLES OF COMBUSTION

COMBUSTION is a chemical reaction in which an oxidant reacts rapidly with a fuel to liberate stored energy as thermal energy, generally in the form of high-temperature gases. Small amounts of electromagnetic energy (light), electric energy (free ions and electrons), and mechanical energy (noise) are also produced during combustion. Except in special applications, the oxidant for combustion is oxygen in the air. The oxidation normally occurs with the fuel in vapor form. One notable exception is oxidation of solid carbon, which occurs directly with the solid phase.

Conventional fuels contain primarily hydrogen and carbon, in elemental form or in various compounds (hydrocarbons). Their complete combustion produces mainly carbon dioxide (CO_2) and water (H_2O); however, small quantities of carbon monoxide (CO) and partially reacted flue gas constituents (gases and liquid or solid aerosols) may form. Most conventional fuels also contain small amounts of sulfur, which is oxidized to sulfur dioxide (SO_2) or sulfur trioxide (SO_3) during combustion, and noncombustible substances such as mineral matter (ash), water, and inert gases. Flue gas is the product of complete or incomplete combustion and includes excess air (if present), but not dilution air (air added to flue gas downstream of the combustion process, such as through the relief opening of a draft hood).

Fuel combustion rate depends on the (1) rate of chemical reaction of combustible fuel constituents with oxygen, (2) rate at which oxygen is supplied to the fuel (mixing of air and fuel), and (3) temperature in the combustion region. The reaction rate is fixed by fuel selection. Increasing the mixing rate or temperature increases the combustion rate.

With **complete combustion** of hydrocarbon fuels, all hydrogen and carbon in the fuel are oxidized to H_2O and CO_2. Generally, complete combustion requires excess oxygen or excess air beyond the amount theoretically required to oxidize the fuel. Excess air is usually expressed as a percentage of the air required to completely oxidize the fuel.

In **stoichiometric combustion** of a hydrocarbon fuel, fuel is reacted with the exact amount of oxygen required to oxidize all carbon, hydrogen, and sulfur in the fuel to CO_2, H_2O, and SO_2. Therefore, exhaust gas from stoichiometric combustion theoretically contains no incompletely oxidized fuel constituents and no unreacted oxygen (i.e., no carbon monoxide and no excess air or oxygen). The percentage of CO_2 contained in products of stoichiometric combustion is the maximum attainable and is referred to as the **stoichiometric CO_2**, **ultimate CO_2**, or **maximum theoretical percentage of CO_2**.

Stoichiometric combustion is seldom realized in practice because of imperfect mixing and finite reaction rates. For economy and safety, most combustion equipment should operate with some excess air. This ensures that fuel is not wasted and that combustion is complete despite variations in fuel properties and supply rates of fuel and air. The amount of excess air to be supplied to any combustion equipment depends on (1) expected variations in fuel properties and in fuel and air supply rates, (2) equipment application, (3) degree of operator supervision required or available, and (4) control requirements. For maximum efficiency, combustion at low excess air is desirable.

Incomplete combustion occurs when a fuel element is not completely oxidized during combustion. For example, a hydrocarbon may not completely oxidize to carbon dioxide and water, but may form partially oxidized compounds, such as carbon monoxide, aldehydes, and ketones. Conditions that promote incomplete combustion include (1) insufficient air and fuel mixing (causing local fuel-rich and fuel-lean zones), (2) insufficient air supply to the flame (providing less than the required amount of oxygen), (3) insufficient reactant residence time in the flame (preventing completion of combustion reactions), (4) flame impingement on a cold surface (quenching combustion reactions), or (5) flame temperature that is too low (slowing combustion reactions).

Incomplete combustion uses fuel inefficiently, can be hazardous because of carbon monoxide production, and contributes to air pollution.

Combustion Reactions

The reaction of oxygen with combustible elements and compounds in fuels occurs according to fixed chemical principles, including

- Chemical reaction equations
- Law of matter conservation: the mass of each element in the reaction products must equal the mass of that element in the reactants
- Law of combining masses: chemical compounds are formed by elements combining in fixed mass relationships
- Chemical reaction rates

Oxygen for combustion is normally obtained from air, which is a mixture of nitrogen, oxygen, small amounts of water vapor, carbon dioxide, and inert gases. For practical combustion calculations, dry air consists of 20.95% oxygen and 79.05% inert gases (nitrogen, argon, etc.) by volume, or 23.15% oxygen and 76.85% inert gases by mass. For calculation purposes, nitrogen is assumed to pass through the combustion process unchanged (although small quantities of nitrogen oxides form). Table 1 lists oxygen and air requirements for stoichiometric combustion and the products of stoichiometric combustion of some pure combustible materials (or constituents) found in common fuels.

Flammability Limits

Fuel burns in a self-sustained reaction only when the volume percentages of fuel and air in a mixture at standard temperature and pressure are within the upper and lower flammability limits (UFL and LFL), also called explosive limits (UEL and LEL; see Table 2). Both temperature and pressure affect these limits. As mixture temperature increases, the upper limit increases and the lower limit decreases. As the pressure of the mixture decreases below atmospheric pressure, the upper limit decreases and the lower limit increases. However, as pressure increases above atmospheric, the upper limit increases and the lower limit is relatively constant.

The preparation of this chapter is assigned to TC 6.10, Fuels and Combustion.

Flammability limits adapted from Coward and Jones (1952). All values corrected to 15.6°C, 104 kPa, dry.

Ignition Temperature

Ignition temperature is the lowest temperature at which heat is generated by combustion faster than it is lost to the surroundings and combustion becomes self propagating (see Table 2). The fuel/air mixture will not burn freely and continuously below the ignition temperature unless heat is supplied, but chemical reaction between the fuel and air may occur. Ignition temperature is affected by a large number of factors.

The ignition temperature and flammability limits of a fuel/air mixture, together, are a measure of the potential for ignition (*Gas Engineers Handbook* 1965).

Combustion Modes

Combustion reactions occur in either continuous or pulse flame modes. **Continuous combustion** burns fuel in a sustained manner as long as fuel and air are continuously fed to the combustion zone and the fuel/air mixture is within the flammability limits. Continuous combustion is more common than pulse combustion and is used in most fuel-burning equipment.

Pulse combustion is an acoustically resonant process that burns various fuels in small, discrete fuel/air mixture volumes in a very rapid series of combustions.

The introduction of fuel and air into the pulse combustor is controlled by mechanical or aerodynamic valves. Typical combustors consist of one or more valves, a combustion chamber, an exit pipe, and a control system (ignition means, fuel-metering devices, etc.). Typically, combustors for warm-air furnaces, hot-water boilers, and commercial cooking equipment use mechanical valves. Aerodynamic valves are usually used in higher-pressure applications, such as thrust engines. Separate valves for air and fuel, a single valve for premixed air and fuel, or multiple valves of either type can be used. Premix valve systems may require a flame trap at the combustion chamber entrance to prevent flashback.

In a mechanically valved pulse combustor, air and fuel are forced into the combustion chamber through the valves under pressures less than 3.5 kPa. An ignition source, such as a spark, ignites the fuel/air mixture, causing a positive pressure build-up in the combustion

Licensed for single user. © 2021 ASHRAE, Inc.

chamber. The positive pressure causes the valves to close, leaving only the exit pipe of the combustion chamber as a pressure relief opening. Combustion chamber and exit pipe geometry determine the resonant frequency of the combustor.

The pressure wave from initial combustion travels down the exit pipe at sonic velocity. As this wave exits the combustion chamber, most of the flue gases present in the chamber are carried with it into the exit pipe. Flue gases remaining in the combustion chamber begin to cool immediately. Contraction of cooling gases and momentum of gases in the exit pipe create a vacuum inside the chamber that opens the valves and allows more fuel and air into the chamber. While the fresh charge of fuel/air enters the chamber, the pressure wave reaches the end of the exit pipe and is partially reflected from the open end of the pipe. The fresh fuel/air charge is ignited by residual combustion and/or heat. The resulting combustion starts another cycle.

Typical pulse combustors operate at 30 to 100 cycles per second and emit resonant sound, which must be considered in their application. The pulses produce high convective heat transfer rates.

Heating Value

Combustion produces thermal energy (heat). The quantity of heat generated by complete combustion of a unit of specific fuel is constant and is called the **heating value**, **heat of combustion**, or **caloric value** of that fuel. A fuel's heating value can be determined by measuring the heat evolved during combustion of a known quantity of the fuel in a calorimeter, or it can be estimated from quantitative chemical analysis of the fuel and the heating values of the various chemical elements in the fuel. For information on calculating heating values, see the sections on Characteristics of Fuel Oils and Characteristics of Coal.

Higher heating value (HHV), **gross heating value**, or **total heating value** includes the latent heat of vaporization and is determined when water vapor in the fuel combustion products is cooled and condensed at standard temperature and pressure. Conversely, **lower heating value (LHV)** or **net heating value** does *not* include latent heat of vaporization. In the United States, when the heating value of a fuel is specified without designating higher or lower, it generally means the higher heating value. (LHV is mainly used for internal combustion engine fuels.)

Heating values are usually expressed in kJ/L or MJ/m^3 for gaseous fuels, MJ/L for liquid fuels, and MJ/kg for solid fuels. Heating values are always given in relation to standard temperature and pressure, usually 16, 20, or 25°C and 101.325 kPa, depending on the particular industry practice. Heating values in the United States and Canada are based on standard conditions of 15.6°C and 101.4 kPa, dry. Heating values of several substances in common fuels are listed in Table 3.

With incomplete combustion, not all fuel is completely oxidized, and the heat produced is less than the heating value of the fuel. Therefore, the quantity of heat produced per unit of fuel consumed decreases (lower combustion efficiency).

Not all heat produced during combustion can be used effectively. The greatest heat loss is the thermal energy of the increased temperature of hot exhaust gases above the temperature of incoming air and fuel. Other heat losses include radiation and convection heat transfer from the outer walls of combustion equipment to the environment.

Altitude Compensation

Air at altitudes above sea level is less dense and has less mass of oxygen per unit volume. The volume concentration of oxygen, however, remains the same as sea level. Therefore, combustion at altitudes above sea level has less available oxygen to burn with the fuel unless compensation is made for the altitude. Combustion occurs, but the amount of excess air is reduced. If excess air is reduced enough by an increase in altitude, combustion is incomplete or ceases.

Table 3 Heating Values of Substances Occurring in Common Fuels

Substance	Molecular Formula	Higher Heating Values,[a] MJ/m^3	Higher Heating Values,[a] MJ/kg	Lower Heating Values,[a] MJ/kg	Specific Density,[b] kg/m^3
Carbon (to CO)	C	—	9.188	9.188	—
Carbon (to CO_2)	C	—	32.780	32.780	—
Carbon monoxide	CO	12.0	10.111	10.111	1.187
Hydrogen	H_2	12.1	142.107	120.075	0.085
Methane	CH_4	37.7	55.533	49.997	0.679

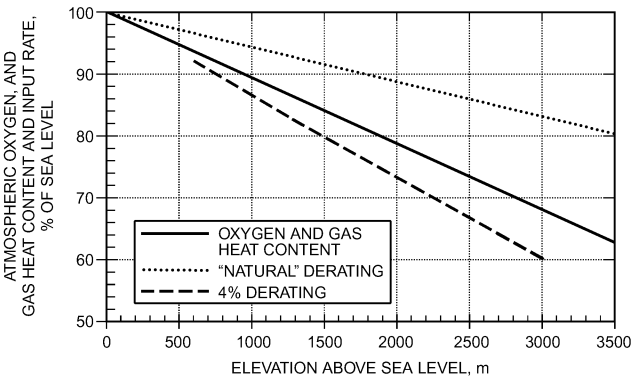
Adapted from *Gas Engineers Handbook* (1965).
[a]All values corrected to 15.6°C, 101.4 kPa, dry. For gases saturated with water vapor at 16°C, deduct 1.74% of value to adjust for gas volume displaced by water vapor.
[b]At 0°C and 101.3 kPa.
[c]*North American Combustion Handbook* (1986).

When gas-fired appliances operate at altitudes substantially above sea level, three notable effects occur (see Chapter 31 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*):

- Oxygen available for combustion is reduced in proportion to the atmospheric pressure reduction.
- With gaseous fuels, the heat of combustion per unit volume of fuel gas (gas heat content) is reduced because of reduced fuel gas density in proportion to the atmospheric pressure reduction.
- Reduced air density affects the performance and operating temperature of heat exchangers and appliance cooling mechanisms.



Altitude compensation matches fuel and air supply rates to attain complete combustion without too much excess air or too much fuel. This can be done at increased altitude by increasing the air supply amount to the combustion zone with a combustion air blower (air compensation), or by decreasing the fuel supply rate to the combustion zone by decreasing the fuel input (derating).

Power burners use combustion air blowers and can increase the air supply rate to compensate for altitude. The combustion zone can be pressurized to attain the same air density in the combustion chamber as that at sea level.

Derating can be used as an alternative to power combustion. U.S. fuel gas codes generally do not require derating of nonpower burners at altitudes up to 600 m. At altitudes above 600 m, many fuel gas codes require that burners be derated 4% for each 300 m above sea level (NFPA/AGA *National Fuel Gas Code*). Chimney or vent operation also must be considered at high altitudes (see Chapter 35 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*).

In addition to reducing the gas heat content of fuel gases, reduced fuel gas density also causes increased gas velocity through flow metering orifices. The net effect is for gas input rate to decrease naturally with increases in altitude, but at less than the rate at which atmospheric oxygen decreases. This effect is one reason that derating is required when appliances are operated at altitudes significantly above sea level. Early research with draft hood-equipped appliances established that appliance input rates should be reduced at the rate of 4% per 300 m above sea level, for altitudes higher than 600 m above sea level (Figure 1).

Licensed for single user. © 2021 ASHRAE, Inc.

Note: Natural derating applies for fixed injector (orifice) size and pressure.

Fig. 1 Altitude Effects on Gas Combustion Appliances

Experience with recently developed appliances with fan-assisted combustion systems demonstrates that the 4% rule may not be required in all cases. It is therefore important to consult the manufacturer's listed appliance installation instructions, which are based on how the combustion system operates, and other factors (e.g., impaired heat transfer).

ASHRAE research projects RP-1182 (Fleck et al. 2007) and RP-1388 (Suchovsky et al. 2011) concluded that the tested induced-draft combustion systems experienced a natural derate of 1.8% (the dotted curve in Figure 1) in gas input rate per 305 m increase in altitude above sea level. This gas input derate for altitude may provide safe combustion operation (less than 400 ppm of CO concentration in air-free flue gas) for induced-draft combustion systems where the combustion air drawn in by the inducer does not participate in gas entrainment or gas orifice outlet pressure that affects the gas rate. Additionally, the gas regulation reference pressure and the gas orifice outlet pressure must be at the same fluidic potential during operation. Alternatively, gas-fired systems where the gas orifice outlet pressure is affected by mechanical draft and not equal to the gas regulation pressure follow a different natural derate. Gas control systems such as the 100% premix systems using a zero-pressure (or near-zero) regulator gas delivery system and the Bernoulli principle for gas entrainment (often called **constant-gas/air-ratio** or **tracking systems**) have a natural derate of 3.1% per 305 m of elevation. These combustion systems can follow a 1:1 ratio with barometric pressure changes (the solid curve in Figure 1). These ASHRAE research projects showed that some gas-fired products as currently designed and constructed can be installed and operated safely and acceptably at some higher altitudes with no modifications to the sea-level gas orifices, gas manifold pressure, etc.

It is important for appliance specifiers to be aware that the heating capacity of appliances is substantially reduced at altitudes significantly above sea level. To ensure adequate delivery of heat, derating of heating capacity must also be considered and quantified.

By definition, fuel gas HHV value remains constant for all altitudes because (in North America) it is based on standard conditions of 101.4 kPa, dry, and 15.6°C. Some fuel gas suppliers at high altitudes (e.g., at Denver, Colorado, at 1524 m) may report fuel gas heat content at local barometric pressure instead of standard pressure. This can be calculated using the following equation:

$$HC = HHV \times \frac{B}{P_s} \quad (1)$$

where

HC = local gas heat content at local barometric pressure and standard temperature conditions, MJ/m^3
HHV = gas higher heating value at standard temperature and pressure of 15.6°C and 101.4 kPa, respectively, MJ/m^3
B = local barometric pressure, kPa (not corrected to sea level: do not use barometric pressure as reported by weather forecasters, because it is corrected to sea level)
P_s = standard pressure = 101.4 kPa

For example, at 1524 m, the barometric pressure is 84.316 kPa. If the HHV of a fuel gas sample is 37.5 MJ/m^3 (at standard temperature and pressure), local gas heat content is 31.21 MJ/m^3 at 84.316 kPa barometric pressure 1524 m above sea level.

$$HC = 37.5 \text{ MJ/m}^3 \times 84.316 \text{ kPa}/101.4 \text{ kPa} = 31.18 \text{ MJ/m}^3$$

Therefore, local gas heat content of a sample of fuel gas can be expressed as 31.18 MJ/m^3 at local barometric pressure of 84.316 kPa and standard temperature, or as 37.5 MJ/m^3 (HHV). Both gas heat contents are correct, but the application engineer must understand the difference to use each one correctly. As described earlier, local heat content HC can be used to determine appliance input rate.

When gas heat value (either HHV or HC) is used to determine gas input rate, the gas pressure and temperature in the meter must also be considered. Add the gage pressure of gas in the meter to the local barometric pressure to calculate the heat content of the gas at the pressure in the meter. Gas temperature in the meter also affects the heat content of the gas in the meter. Gas heat value is directly proportional to gas pressure and inversely proportional to its absolute temperature in accordance with the perfect gas laws, as shown in the following example calculations for gas input rate with either the HHV or local heat content method.

Example 1. Calculate the gas input rate for 37.5 MJ/m^3 HHV fuel gas, 2.800 m^3/h volumetric flow rate of 24°C fuel gas at 84.316 kPa barometer pressure (1525 m altitude) with 1.700 kPa fuel gas pressure in the gas meter.

HHV Method:

$$Q = 0.2778 \text{HHV} \times \text{VFR}_s$$

where

Q = fuel gas input rate, kW
0.2778 = conversion factor, MJ/h to kW
HHV = fuel gas higher heating value at standard temperature and pressure, MJ/m^3
VFR_s = fuel gas volumetric flow rate adjusted to standard temperature and pressure, m^3/h
= $\text{VFR}(T_s \times P)/(T \times P_s)$
VFR = fuel gas volumetric flow rate at local temperature and pressure conditions, m^3/h
T_s = standard temperature, 288.75 K (15.6°C + 273.15)
P = gas meter absolute pressure, kPa (local barometer pressure + gas pressure in meter relative to barometric pressure) = 84.316 kPa + 1.700 kPa = 86.016 kPa gas meter absolute pressure
T = absolute temperature of fuel gas, K (fuel gas temperature in °C + 273.15 K)
P_s = standard pressure, 101.4 kPa

Substituting given values into the equation for VFR_s gives

$$\text{VFR}_s = \frac{2.800 \text{ m}^3/\text{h} \times 288.75 \text{ K} \times 86.016 \text{ kPa}}{(24.00°\text{C} + 273.15 \text{ K})101.4 \text{ kPa}} = 2.308 \text{ m}^3/\text{h}$$

Then,

$$Q = 0.2778 \times 37.5 \text{ MJ/m}^3 \times 2.308 \text{ m}^3/\text{h} = 24.061 \text{ kW}$$

Local Gas Heat Content Method: The local gas heat content is simply the HHV adjusted to local gas meter pressure and temperature conditions. The gas input rate is simply the observed volumetric gas flow rate times the local gas heat content.

$$Q = 0.2778 \text{HC} \times \text{VFR}$$

where

Q = fuel gas input rate, kW

Licensed for single user. © 2021 ASHRAE, Inc.

0.2778 = conversion factor, MJ/h to kW
HC = fuel gas heat content at local gas meter pressure and temperature conditions, MJ/m^3
VFR = fuel gas volumetric flow rate, referenced to local gas meter pressure and temperature conditions, m^3/h

$$HC = HHV(T_s \times P)/(T \times P_s)$$

T_s = standard temperature, 288.75 K (15.6°C + 273.15 K)
P = gas meter absolute pressure, kPa (local barometer pressure + gas pressure in gas meter relative to barometric pressure)
P_s = standard pressure = 101.4 kPa
P_l = local barometric pressure = 84.316 kPa
T = absolute temperature of fuel gas, 297.15 K (24.00°C fuel gas temperature + 273.15 K)

Substituting given values into the equation for HC gives

$$HC = \frac{37.5 \times 288.75(84.316 + 1.700)}{297.15 \times 101.4} = 30.91 \text{ MJ/m}^3$$

Then,

$$Q = 0.2778 \times 30.91 \text{ MJ/m}^3 \times 2.800 \text{ m}^3/\text{h} = 24.044 \text{ kW}$$

The gas input rate is about the same for both calculation methods.

2. FUEL CLASSIFICATION

Generally, hydrocarbon fuels are classified according to physical state (gas, liquid, or solid). Different types of combustion equipment are usually needed to burn fuels in the different physical states. Gaseous fuels can be burned in premix or diffusion burners. Liquid fuel burners must include a means for atomizing or vaporizing fuel and must provide adequate mixing of fuel and air. Solid fuel combustion equipment must (1) heat fuel to vaporize sufficient volatiles to initiate and sustain combustion, (2) provide residence time to complete combustion, and (3) provide space for ash containment.

Principal fuel applications include space heating and cooling of residential, commercial, industrial, and institutional buildings; service water heating; steam generation; and refrigeration. Major fuels for these applications are natural and liquefied petroleum gases (LPG), fuel oils, diesel and gas turbine fuels (for on-site energy applications), and coal. Fuels of limited use, such as manufactured gases, kerosene, liquid fuels derived from biological materials (wood, vegetable oils, and animal fat products), briquettes, wood, and coke, are not discussed here.

Fuel choice is based on one or more of the following:

Fuel factors

- Availability, including dependability of supply
- Convenience of use and storage
- Economy
- Cleanliness, including amount of contamination in unburned fuel [affecting (1) usability in fuel-burning equipment and (2) environmental impact]

Combustion equipment factors

- Operating requirements
- Cost
- Service requirements
- Ease of control

3. GASEOUS FUELS

Although various gaseous fuels have been used as energy sources in the past, heating and cooling applications are presently limited to natural gas and liquefied petroleum gases.

Types and Properties

Natural Gas. This is a nearly odorless, colorless gas that accumulates in the upper parts of oil and gas reservoirs. Raw natural gas is a mixture of methane (55 to 98%), higher hydrocarbons (primarily ethane), and noncombustible gases. Some constituents, principally water vapor, hydrogen sulfide, helium, liquefied petroleum gases, and gasoline, are removed before distribution.

Natural gas used as fuel typically contains methane, CH_4 (70 to 96%); ethane, C_2H_6 (1 to 14%); propane, C_3H_8 (0 to 4%); butane, C_4H_{10} (0 to 2%); pentane, C_5H_{12} (0 to 0.5%); hexane, C_6H_{14} (0 to 2%); carbon dioxide, CO_2 (0 to 2%); oxygen, O_2 (0 to 1.2%); and nitrogen, N_2 (0.4 to 17%).

The composition of natural gas depends on its geographical source. Because the gas is drawn from various sources, the composition of gas distributed in a given location can vary slightly, but a fairly constant heating value is usually maintained for control and safety. Local gas utilities are the best sources of current gas composition data for a particular area.

Heating values of natural gases vary from 34 to 45 MJ/m^3; the usual range is 37.3 to 39.1 MJ/m^3 at sea level. The heating value for a particular gas can be calculated from the composition data and values in Table 3.

For safety purposes, odorants (e.g., mercaptans) are added to natural gas and LPG to give them noticeable odors.

Liquefied Petroleum Gases (LPG). These gases consist primarily of propane and butane, and are usually obtained as a by-product of oil refinery operations or by stripping liquefied petroleum gases from the natural gas stream. Propane and butane are gaseous under usual atmospheric conditions, but can be liquefied under moderate pressures at normal temperatures.

Commercial propane consists primarily of propane but generally contains about 5 to 10% propylene. Its heating value is about 50.15 MJ/kg, about 93 MJ/m^3 of gas, or about 25.4 GJ/m^3 of liquid propane. At atmospheric pressure, commercial propane has a boiling point of about –42°C. The low boiling point of propane allows it to be used during winter in the northern United States and southern Canada. Tank heaters and vaporizers allow its use also in colder climates and where high fuel flow rates are required. American Society for Testing and Materials (ASTM) *Standard* D1835 and Gas Processors Association (GPA) *Standard* 2140, which are similar, provide formulating specifications for required properties of liquefied petroleum gases at the time of delivery. Propane is shipped in cargo tank vehicles, rail cars, and barges. It is stored at consumer sites in tanks that comply with requirements of the ASME *Boiler and Pressure Vessel Code* or transportable cylinders that comply with requirements of the U.S. Department of Transportation.

HD-5 propane is a special LPG product for use in internal combustion engines under moderate to high severity. Its specifications are included in ASTM *Standard* D1835 and GPA *Standard* 2140.

Propane/air mixtures are used in place of natural gas in small communities and by natural gas companies to supplement normal supplies at peak loads. Table 4 lists heating values and densities for various fuel/air ratios.

Commercial butane consists primarily of butane but may contain up to 5% butylene. It has a heating value of about 49.3 MJ/kg, about 120 MJ/m^3 of gas, or about 28.4 GJ/m^3 of liquid butane. At atmospheric pressure, commercial butane has a relatively high boiling point of about 0°C. Therefore, butane cannot be used in cold weather unless the gas temperature is maintained above 0°C or the partial pressure is decreased by dilution with a gas having a lower boiling point. Butane is usually available in bottles, tank trucks, or tank cars, but not in cylinders.

Butane/air mixtures are used in place of natural gas in small communities and by natural gas companies to supplement normal supplies at peak loads. Table 4 lists heating values and densities for various fuel/air ratios.

Commercial propane/butane mixtures with various ratios of propane and butane are available. Their properties generally fall between those of the unmixed fuels.

Table 4 Propane/Air and Butane/Air Gas Mixtures

Heating Value, MJ/m³	Propane/Air[a]			Butane/Air[b]		
	% Gas	% Air	Density, kg/m³	% Gas	% Air	Density, kg/m³
18	19.16	80.84	1.41	14.81	85.19	1.48
22	23.41	76.59	1.44	18.11	81.89	1.52
26	27.67	72.33	1.46	21.40	78.60	1.56
30	31.93	68.07	1.49	24.69	75.31	1.60
34	36.18	63.82	1.52	27.98	72.02	1.64
38	40.44	59.56	1.54	31.27	68.73	1.68
42	44.70	55.30	1.57	34.57	65.43	1.72
46	48.95	51.05	1.60	37.86	62.14	1.76
50	53.21	46.79	1.63	41.15	58.85	1.80
54	57.47	42.53	1.65	44.44	55.56	1.84
58	61.72	38.28	1.68	47.74	52.26	1.88
62	65.98	34.02	1.71	51.03	48.97	1.92
66	70.24	29.76	1.73	54.32	45.68	1.96

Adapted from *Gas Engineers Handbook* (1965).
Air density at 0°C and 101.325 kPa is 1.292 kg/m³.
[a]Values used for calculation: 93.97 MJ/m³; density = 1.92 kg/m³.
[b]Values used for calculation: 121.5 MJ/m³; density = 2.53 kg/m³.

Manufactured gases are combustible gases produced from coal, coke, oil, liquefied petroleum gases, or natural gas. For more detailed information, see the *Gas Engineers Handbook* (1965). These fuels are used primarily for industrial in-plant operations or as specialty fuels (e.g., acetylene for welding).

Renewable Gases. There are two primary processes that produce renewable gas from various feedstocks: anaerobic digestion and thermal gasification. Both processes are discussed here in general.

Anaerobic Digestion (AD). In this process, complex organic matter (source material) is broken down into simpler constituents, directly through microbial action and in the absence of oxygen. The degradation process usually occurs in some form of tank, called a **digester** or **reactor**. Organic matter, perhaps first pretreated by grinding or by mechanical or chemical hydrolysis, enters the tank and is held there for a predefined length of time. For systems based on animal manure, this time ranges from a few days to a few weeks; for systems that use energy crops, residence time can be up to several tens of days. During that period, microbial activity breaks down the organic matter, and the resultant gaseous products contain a large fraction of methane and carbon dioxide along with trace amounts of other gases. Eventually, the material is expelled from the digester and replaced by new feed matter to continue the digestion/degradation process. The new organic matter may replace the entirety of the resident matter in batch, or it may replace it semicontinuously, depending on the reactor and on the collection and processing of the source matter.

The four stages of anaerobic digestion are as follows:

1. In **hydrolysis**, bacteria liquefy and break down organic matter comprised of complex organic polymers and cell structures. The end products are organic molecules that consist primarily of sugars, amino acids, peptides, and fatty acids.
2. In **acidogenesis**, acid-forming bacteria break down the products of the hydrolytic stage, forming volatile organic acids, CO_2, hydrogen, and ammonia.
3. Next, in **acetogenesis**, bacteria convert the volatile organic acids from acidogenesis into acetic acid (CH_3COOH) and acetate, CO_2, and hydrogen.
4. Finally, **methanogenesis** uses methane-producing bacteria to change CO_2 and acetic acid (products of the acidogenic and acetogenic stages) into methane (CH_4). The resultant gas yield consists primarily of CH_4, CO_2, and other trace gases such as hydrogen sulfide (H_2S).

Wastewater treatment plant (WWTP) gases are generated from waste liquids and solids from household or commercial water usage or from industrial processes. Depending on the architecture of the sewer system and local regulation, it may also contain stormwater from roofs, streets, or other runoff areas. The contents may include anything expelled (legally or not) from a household that enters the drains. If stormwater is included in the wastewater sewer flow, it may also contain components collected during runoff (e.g., soil, metals, organic compounds, animal waste, oils, solid debris such as leaves and branches).

Processing influent to a large wastewater treatment plant typically has three stages: mechanical, biological, and sometimes chemical processing. The goal of such treatments is to prepare solids (treated sludge) and liquids (treated effluent) output from the WWTP that is environmentally safe and able to be landfilled (treated solids) or returned to the environment (treated effluent). One step in the processing of the wastewater sludge may be anaerobic digestion, from which methane can be produced.

Landfill gas (LFG) derives from municipal solid waste (MSW) in landfills. In the United States, the primary federal law currently controlling disposal of solid and hazardous waste is the Resource Conservation and Recovery Act (RCRA), which sets criteria under which landfills can accept municipal solid waste and nonhazardous industrial solid waste. It also prohibits open dumping of waste, and ensures that hazardous waste is managed from the time of its creation to the time of its disposal.

For energy production, MSW can be used in either of two ways: it can be gasified directly through thermochemical processes [see the section on Thermal Gasification (TG)], or it can be deposited into a landfill and undergo AD. Although most surveys indicate the material composition of all landfill constituents, the important components of MSW for the production of landfill gas are the organic fractions, which form the substrates that anaerobically decompose in the landfill. Typical or approximate contents of the organic fractions of MSW appear in Table 5.

Landfill gas is the result of these anaerobic processes acting on the organic matter within a landfill. In a sense, the landfill itself substitutes for an anaerobic digester tank: a closed volume that contains putrescible matter and over time becomes devoid of oxygen.

Methane and carbon dioxide are the principal components of the gas, though the overall composition of raw LFG can vary depending on the materials in the landfill: it can contain significant amounts of hydrogen sulfide as well as trace amounts of ammonia, mercury, chlorine, fluorine, siloxanes, and volatile metallic compounds.

Variation in source MSW, its organic contents, temperature conditions, moisture conditions, compaction densities, landfill operational procedures, and other landfill attributes account for variations in LFG content. Typical compounds and their reported concentration ranges are shown in Table 6. Methane concentration is generally reported as being around 55 mol%, and carbon dioxide is often measured at 40%. Nitrogen, hydrogen, oxygen, and hydrogen sulfide are found in smaller but significant quantities.

The composition of raw biogas can vary depending on the materials being digested. Methane and carbon dioxide are the principal components of landfill gas, though the overall composition of raw LFG can contain significant amounts of H_2S as well as trace amounts of ammonia, mercury, chlorine, fluorine, siloxanes, and volatile metallic compounds (EPA 2017).

However, the composition of **biogas generated from dairy manure** tends to be more consistent because the dairy industry is regulated as a producer of milk for human consumption. Typical compounds and their reported concentration ranges for digester-based biogas are shown in Table 7. Methane concentration can be as high as 70% but is generally reported at around 60%. Landfill gas, unless the landfill is specifically designed for gas production, typically has a slightly lower methane fraction (e.g., around 55%).

Table 5 Components of Organic Portion of Municipal Solid Waste

Component Composition	Mass, %
Moisture	20.7
Cellulose, sugar, starch	46.6
Lipids	4.5
Protein	2.1
Other organics	1.2
Inert materials	24.9
Total	**100**

Table 6 Landfill Gas Composition

Compound	mol%
Methane (CH_4)	45 to 60
Carbon dioxide (CO_2)	40 to 60
Nitrogen (N_2)	2 to 5
Hydrogen (H_2)	0 to 0.2
Carbon monoxide (CO)	0 to 0.2
Oxygen (O_2)	0.1 to 1
Sulfides, disulfides, mercaptans, etc.	0 to 1
Ammonia (NH_3)	0.1 to 1
Trace elements, amines, sulfur compounds, nonmethane volatile organic carbons halocarbons	0.01 to 0.6

Adding food wastes into a manure-based digester (**codigestion**) seems to improve biogas production and may increase methane concentration, but is not addressed in this chapter. CO_2, the other major biogas component, is often measured around 40%. Nitrogen, hydrogen, oxygen, and H_2S are found in smaller quantities.

Similarly to natural gas, biogas derived from biomass feedstocks also must undergo one or more cleanup processes to remove unwanted components and to upgrade it suitably for natural gas pipelines. Quality control is required to prevent or minimize entry of raw, unconditioned biogas or less-than-pipeline-quality biomethane into the natural gas grid. Many methods and processes can be used to remove contaminants from subquality gas streams. Some are appropriate for use on farms, and others are only economical at gas flows measuring 30 000 m^3 per day or more and where sulfur removal rates are measured in megagrams per day. The ability of a process to remove unwanted compounds depends on many factors, and assessment of the true practicality of a method for a given application requires careful evaluation.

Thermal Gasification (TG). This process encompasses a fairly broad range of processes and reactions that convert carbonaceous feedstocks (coal, heavy oils, wood, biomass, sludge, etc.) into a mixture of gases, primarily hydrogen, carbon monoxide, steam, carbon dioxide, some methane, small amounts of ethane and higher hydrocarbons, small amounts of hydrogen sulfide, and nitrogen (if gasification is conducted with air). Depending on feedstock and operating conditions, TG of biomass typically generates tars and oils that are undesirable by-products.

Thermal gasification is conducted in reducing (substoichiometric or incompletely combusting) atmospheres. Some of the process heat for the endothermic gasification reactions is typically provided by burning some of the carbon in the feedstock. Process heating can be direct or indirect. Indirect heating of the gasifier is called **allthermal gasification**. A typical range of syngas compositions from oxygen- or air-blown operation is presented in Table 8.

This mixture of gases is known as synthesis gas or **syngas**, and can be further catalytically converted into methane to generate refinery gas (RG). The syngas can also be converted into liquid products by Fischer-Tropsch synthesis [see DOE (2017) for a description] for use as transportation fuel, or transformed into a host of chemical products such as methanol, dimethyl ether, fuel gas/

Table 7 Typical Compounds and Concentrations in Biogas from Anaerobic Digester

Compound	Concentration
Methane (CH_4)	54 to 70%
Carbon dioxide (CO_2)	27 to 45%
Nitrogen (N_2)	0.5 to 3%
Hydrogen (H_2)	1 to 10%
Carbon monoxide (CO)	0 to 0.1%
Oxygen (O_2)	0 to 0.1%
Hydrogen sulfide (H_2S)	600 to 7000+ ppm

Table 8 Typical Compounds and Concentrations Found in Syngas from Thermal Gasification

Compound Typical Range	Air-Blown Fixed Bed	Steam-Blown Fluidized Bed	Oxygen-Blown Entrained Flow
Calorific value, MJ/m^3	4 to 6	12 to 14	10 to 12
Hydrogen (H_2), mol%	11 to 16	35 to 45	23 to 28
Carbon monoxide (CO), mol%	13 to 18	22 to 25	45 to 55
Carbon dioxide (CO_2), mol%	12 to 16	20 to 23	10 to 15
Methane (CH_4), mol%	2 to 6	9 to 11	<1
Nitrogen (N_2), mol%	45 to 60	<1	<5

town gas, ethylene/propylene, or acetic acid. It can also be combusted directly in a gas turbine to drive a generator. In some cases, a catalyst is included with the feedstock to accelerate reactions and allow a reduced operating temperature. TG can be carried out at temperatures in the range of 650 to 1100°C and at pressures ranging from ambient to greater than 7000 kPa. If the TG process is conducted at ambient or fairly low pressure, then the product RG must be compressed so it can be injected into the transmission or distribution line at the appropriate pressure.

4. LIQUID FUELS

Significant liquid fuels include various fuel oils for firing combustion equipment and engine fuels for on-site energy systems. Liquid fuels, with few exceptions, are mixtures of hydrocarbons derived by refining crude petroleum. In addition to hydrocarbons, crude petroleum usually contains small quantities of sulfur, oxygen, nitrogen, vanadium, other trace metals, and impurities such as water and sediment. Refining produces a variety of fuels and other products. Nearly all lighter hydrocarbons are refined into fuels (e.g., liquefied petroleum gases, gasoline, kerosene, jet fuels, diesel fuels, light heating oils). Heavy hydrocarbons are refined into residual fuel oils and other products (e.g., lubricating oils, waxes, petroleum coke, asphalt).

Crude petroleums from different oil fields vary in hydrocarbon molecular structure. Crude is paraffin-base (principally chain-structured paraffin hydrocarbons), naphthene- or asphaltic-base (containing relatively large quantities of saturated ring-structural naphthenes), aromatic-base (containing relatively large quantities of unsaturated, ring-structural aromatics, including multi-ring compounds such as asphaltenes), or mixed- or intermediate-base (between paraffin- and naphthene-base crudes). Except for heavy fuel oils, the crude type has little significant effect on resultant distillate products and combustion applications.

Types of Fuel Oils

Fuel oils for heating are broadly classified as **distillate fuel oils** (lighter oils) or **residual fuel oils** (heavier oils). ASTM *Standard* D396 has specifications for fuel oil properties that subdivide the oils into various grades. Grades No. 1 and 2 are distillates; grades 4, 5 (Light), 5 (Heavy), and 6 are residual. Specifications for the grades are based on required characteristics of fuel oils for use in different types of burners.

Licensed for single user. © 2021 ASHRAE, Inc.

Grade No. 1 is a light distillate intended for vaporizing-type burners. High volatility is essential to continued evaporation with minimum residue. This fuel is also used in extremely cold climates for residential heating using pressure-atomizing burners.

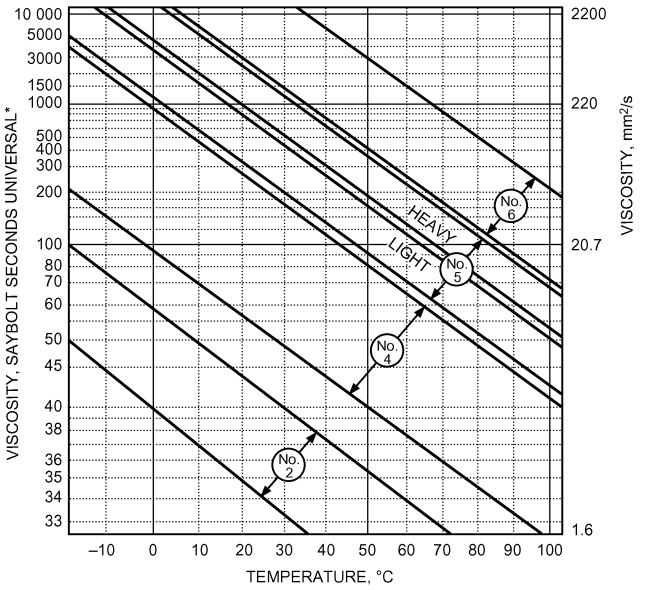
Grade No. 2 is heavier than No. 1 and is used primarily with pressure-atomizing (gun) burners that spray oil into a combustion chamber. Vapor from the atomized oil mixes with air and burns. This grade is used in most domestic burners and many medium-capacity commercial/industrial burners. A dewaxed No. 2 oil with a pour point of –50°C is supplied only to areas where regular No. 2 oil would jell. Grade No. 2—low sulfur is a relatively new category that has a sulfur content of 0.05%. Lower fuel sulfur content reduces fouling rates of boiler heat exchangers (Butcher et al. 1997).

Grade No. 4 is an intermediate fuel that is considered either a heavy distillate or a light residual. Intended for burners that atomize oils of higher viscosity than domestic burners can handle, its permissible viscosity range allows it to be pumped and atomized at relatively low storage temperatures.

Grade No. 5 (*Light*) is a residual fuel of intermediate viscosity for burners that handle fuel more viscous than No. 4 without preheating. Preheating may be necessary in some equipment for burning and, in colder climates, for handling.

Grade No. 5 (*Heavy*) is a residual fuel more viscous than No. 5 (Light), but intended for similar purposes. Preheating is usually necessary for burning and, in colder climates, for handling.

Grade No. 6, sometimes referred to as Bunker C, is a high-viscosity oil used mostly in commercial and industrial heating. It requires preheating in the storage tank to allow pumping, and additional preheating at the burner to allow atomizing.



Low-sulfur residual oils are marketed in many areas to allow users to meet sulfur dioxide emission regulations. These fuel oils are produced (1) by refinery processes that remove sulfur from the oil (hydrodesulfurization), (2) by blending high-sulfur residual oils with low-sulfur distillate oils, or (3) by a combination of these methods. These oils have significantly different characteristics from regular residual oils. For example, the viscosity/temperature relationship can be such that low-sulfur fuel oils have viscosities of No. 6 fuel oils when cold, and of No. 4 when heated. Therefore, normal guidelines for fuel handling and burning can be altered when using these fuels.

Another liquid fuel of increasing interest is biodiesel. It is made from biological sources (e.g., vegetable oils, used cooking oils, tallow). ASTM *Standard* D6751 addresses biodiesel; requirements are largely similar to those for petroleum diesel (cetane number, flash point, etc.; see the section on Types and Properties of Liquid Fuels for Engines). In practice, biodiesel is almost always blended, most often with ASTM heating oils when used for stationary heating applications, because of cost and cold-flow properties of 100% biodiesel. However, the benefits of a renewable fuel that has very low net carbon dioxide emission in its life cycle, reduced particulate and sulfur emissions, and lower NO_x emissions in many heating applications balance the need for mixing.

Fuel oil grade selection for a particular application is usually based on availability and economic factors, including fuel cost, clean air requirements, preheating and handling costs, and equipment cost. Installations with low firing rates and low annual fuel consumption cannot justify the cost of preheating and other methods that use residual fuel oils. Large installations with high annual fuel consumption cannot justify the premium cost of distillate fuel oils.

Characteristics of Fuel Oils

Characteristics that determine grade classification and suitability for given applications are (1) viscosity, (2) flash point, (3) pour point, (4) water and sediment content, (5) carbon residue, (6) ash, (7) distillation qualities or distillation temperature ranges, (8) density, (9) sulfur content, (10) heating value, (11) carbon/ hydrogen content, (12) aromatic content, and (13) asphaltene content. Not all of these are included in ASTM *Standard* D396.

* 1 Saybolt Second (SSU, or SUS) = time required for 60 mL to gravity-flow through Saybolt universal viscometer.

Fig. 2 Approximate Viscosity of Fuel Oils

Viscosity is an oil's resistance to flow. It is significant because it indicates the ease with which oil flows or can be pumped and the ease of atomization. Differences in fuel oil viscosities are caused by variations in the concentrations of fuel oil constituents and different refining methods. Approximate viscosities of fuel oils are shown in Figure 2.

Flash point is the lowest temperature to which an oil must be heated for its vapors to ignite in a flame. Minimum permissible flash point is usually prescribed by state and municipal laws.

Pour point is the lowest temperature at which a fuel can be stored and handled. Fuels with higher pour points can be used when heated storage and piping facilities are provided.

Water and **sediment content** should be low to prevent fouling the facilities. Sediment accumulates on filter screens and burner parts. Water in distillate fuels can cause tanks to corrode and emulsions to form in residual oil.

Carbon residue is obtained by a test in which the oil sample is destructively distilled in the absence of air. When commercial fuels are used in proper burners, this residue has almost no relationship to soot deposits, except indirectly when deposits are formed by vaporizing burners.

Ash is the noncombustible material in an oil. An excessive amount indicates the presence of materials that cause high wear on burner pumps.

The **distillation** test shows the volatility and ease of vaporization of a fuel.

Relative density is the ratio of the density of a fuel oil to the density of water at a specific temperature. Relative densities cover a range in each grade, with some overlap between distillate and residual grades.

Air pollution considerations are important in determining the allowable **sulfur content** of fuel oils. Sulfur content is frequently limited by legislation aimed at reducing sulfur oxide emissions from combustion equipment; usual maximum allowable sulfur content levels are 1.0, 0.5, or 0.3%. Table 9 lists sulfur levels of some marketed fuel oils. Research (Lee et al. 2002a, 2002b) suggests that fuel

Licensed for single user. © 2021 ASHRAE, Inc.

Table 9 Sulfur Content of Marketed Fuel Oils

Grade of Oil	No. 1	No. 2	No. 4	No. 5 (Light)	No. 5 (Heavy)	No. 6
Total fuel samples	31	61	13	15	16	96
Sulfur content, % mass						
minimum	0.001	0.03	0.46	0.90	0.57	0.32
maximum	0.120	0.50	1.44	3.50	2.92	4.00
average	0.023	0.20	0.83	1.46	1.46	1.41

over 0.3%	0	17	13	15	16	96
over 0.5%	0	2	11	15	16	93
over 1.0%	0	0	3	9	11	60
over 3.0%	0	0	0	2	0	8

Data for No. 1 and No. 2 oil derived from Dickson and Sturm (1994).
Data for No. 4, 5, and 6 oil derived from Shelton (1974).

Table 10 Typical Density and Higher Heating Value of Standard Grades of Fuel Oil

Grade No.	Density, kg/m^3	Higher Heating Value, GJ/m^3
1	833 to 800	38.2 to 37.0
2	874 to 834	39.5 to 38.2
4	933 to 886	41.3 to 39.9
5L	951 to 921	41.8 to 40.9
5H	968 to 945	42.4 to 41.6
6	1012 to 965	43.5 to 42.2

sulfur content affects the sulfate content of particulate emissions, which are reported to be associated with adverse health effects.

Sulfur in fuel oils is also undesirable because sulfur compounds in flue gas are corrosive. Although low-temperature corrosion can be minimized by maintaining the stack at temperatures above the dew point of the flue gas, this limits the overall thermal efficiency of combustion equipment. The presence of sulfur oxides in the flue gas raises the dew point temperature (see the section on Combustion Calculations).

For certain industrial applications (e.g., direct-fired metallurgy, where work is performed in the combustion zone), fuel sulfur content must be limited because of adverse effects on product quality. Sulfur contents of typical fuel oils are listed in Table 9.

Heating value is an important property, although ASTM *Standard* D396 does not list it as one of the criteria for fuel oil classification. Table 10 shows the relationship between heating value and density for several oil grades. In the absence of more specific data, heating values can be calculated as derived from the *North American Combustion Handbook* (1978):

$$\text{Higher heating value, MJ/kg} = 51.92 - 8.79 \times 10^{-6}\rho^2 \quad (2)$$

Distillate fuel oils (grades 1 and 2) have a **carbon/hydrogen content** of 84 to 86% carbon, with the remainder predominantly hydrogen. Heavier residual fuel oils (grades 4, 5, and 6) may contain up to 88% carbon and as little as 11% hydrogen. An approximate relationship for determining the hydrogen content of fuel oils is

$$\text{Hydrogen, \%} = 26 - (15 \times \text{Relative density}) \quad (3)$$

ASTM *Standard* D396 is more a classification than a specification, distinguishing between six generally nonoverlapping grades, one of which characterizes any commercial fuel oil. Quality is not defined, as a refiner might control it; for example, the standard lists the distillation temperature 90% point for grade No. 2 as having a maximum of 338°C, whereas commercial practice rarely exceeds 315°C.

Types and Properties of Liquid Fuels for Engines

The primary stationary engine fuels are diesel and gas turbine oils, natural gases, and LPGs. Other fuels include sewage gas, manufactured gas, and other commercial gas mixtures. Gasoline and the JP series of gas turbine fuels are rarely used for stationary engines.

Only properties of diesel and gas turbine fuel oils are covered here; properties of natural and liquefied petroleum gases are found in the section on Gaseous Fuels. For properties of gasolines and JP turbine fuel, consult texts on internal combustion engines and gas turbines. Properties of currently marketed gasolines can be found in ASTM *Standard* D4814.

Properties of the three **grades of diesel fuel oils** (1-D, 2-D, and 4D) are listed in ASTM *Standard* D975.

Grade No. 1-D includes the class of volatile fuel oils from kerosene to intermediate distillates. They are used in high-speed engines with frequent and relatively wide variations in loads and speeds and where abnormally low fuel temperatures are encountered.

Grade No. 2-D includes the class of lower-volatility distillate gas oils. They are used in high-speed engines with relatively high loads and uniform speeds, or in engines not requiring fuels with the higher volatility or other properties specified for grade No. 1-D.

Grade No. 4-D covers the more viscous distillates and blends of these distillates with residual fuel oils. They are used in low- and medium-speed engines involving sustained loads at essentially constant speed.

Property specifications and test methods for grade No. 1-D, 2-D, and 4-D diesel fuel oils are essentially identical to specifications of grade No. 1, 2, and 4 fuel oils, respectively. However, diesel fuel oils have an additional specification for **cetane number**, which measures ignition quality and influences combustion roughness. Cetane number requirements depend on engine design, size, speed and load variations, and starting and atmospheric conditions. An increase in cetane number over values actually required does not improve engine performance. Thus, the cetane number should be as low as possible to ensure maximum fuel availability. ASTM *Standard* D975 provides several methods for estimating cetane number from other fuel oil properties.

ASTM *Standard* D2880 for gas turbine fuel oils relates gas turbine fuel oil grades to fuel and diesel fuel oil grades. Test methods for determining properties of gas turbine fuel oils are essentially identical to those for fuel oils. However, gas turbine specifications limit quantities of some trace elements that may be present, to prevent excessive corrosion in gas turbine engines. For a detailed discussion of fuels for gas turbines and combustion in gas turbines, see Chapters 5 and 9, respectively, in Hazard (1971).

5. SOLID FUELS

Solid fuels include coal, coke, wood, and waste products of industrial and agricultural operations. Of these, only coal is widely used for heating and cooling applications.

Coal's complex composition makes classification difficult. Chemically, coal consists of carbon, hydrogen, oxygen, nitrogen, sulfur, and a mineral residue, ash. Chemical analysis provides some indication of quality, but does not define its burning characteristics sufficiently. Coal users are principally interested in the available energy per unit mass of coal and the amount of ash and dust produced, but are also interested in burning characteristics and handling and storing properties. A description of coal qualities and characteristics from the U.S. Bureau of Mines as well as other information can be obtained from the U.S. Geological Survey at energy.er.usgs.gov/products/databases/USCoal/index.htm and the Energy Information Administration at www.eia.doe.gov/fuelcoal.html.

Table 11 Classification of Coals by Rank[a]

Class	Group	Limits of Fixed Carbon or Energy Content, Mineral-Matter-Free Basis	Requisite Physical Properties
I Anthracite	1. Metaanthracite	Dry FC, 98% or more (Dry VM, 2% or less)	Nonagglomerating
	2. Anthracite	Dry FC, 92% or more, and less than 98% (Dry VM, 8% or less, and more than 2%)	
	3. Semianthracite	Dry FC, 86% or more, and less than 92% (Dry VM, 14% or less, and more than 8%)	
II Bituminous[d]	1. Low-volatile bituminous coal	Dry FC, 78% or more, and less than 86% (Dry VM, 22% or less, and more than 14%)	Either agglomerating[b] or nonweathering[f]
	2. Medium-volatile bituminous coal	Dry FC, 69% or more, and less than 78% (Dry VM, 31% or less, and more than 22%)	
	3. High-volatile Type A bituminous coal	Dry FC, less than 69% (Dry VM, more than 31%), and moist,[c] about 32.6 MJ/kg[e] or more	
	4. High-volatile Type B bituminous coal	Moist,[c] about 30.2 MJ/kg or more, and less than 32.6 MJ/kg[e]	
	5. High-volatile Type C bituminous coal	Moist,[c] about 25.6 MJ/kg or more, and less than 30.2 MJ/kg[e]	
III Subbituminous	1. Subbituminous Type A coal	Moist,[c] about 25.6 MJ/kg or more, and less than 30.2 MJ/kg[e]	Both weathering and nonagglomerating[b]
	2. Subbituminous Type B coal	Moist,[c] about 22.1 MJ/kg or more, and less than 25.6 MJ/kg[e]	
	3. Subbituminous Type C coal	Moist,[c] about 19.3 MJ/kg or more, and less than 22.1 MJ/kg[e]	
IV Lignitic	1. Lignite	Moist,[c] less than 19.3 MJ/kg	Consolidated
	2. Brown coal	Moist,[c] less than 19.3 MJ/kg	Unconsolidated

Source: Data from ASTM *Standard* D388.
FC = fixed carbon; VM = volatile matter; MMF = mineral-matter-free
[a]Classification does not include a few coals of unusual physical and chemical properties that come within limits of fixed carbon or energy content of high-volatile bituminous and subbituminous ranks. All these coals either contain less than 48% dry, MMF FC, or have more than about 36.1 MJ/kg, which is moist, MMF.
[b]If agglomerating, classify in group 1 of class II.
[c]*Moist* refers to coal containing natural bed moisture but without visible water on coal surface.
[d]There may be noncaking varieties in each group of class II.
[e]Coals with 69% or more fixed carbon on dry, MMF basis are classified according to FC, regardless of energy content.
[f]There are three varieties of coal in group 5: variety 1, agglomerating and nonweathering; variety 2, agglomerating and weathering; and variety 3, nonagglomerating and nonweathering.

Types of Coals

Commonly accepted definitions for classifying coals are listed in Table 11. This classification is arbitrary because there are no distinct demarcation lines between coal types.

Anthracite is a clean, dense, hard coal that creates little dust in handling. It is comparatively difficult to ignite, but burns freely once started. It is noncaking and burns uniformly and smokelessly with a short flame.

Semianthracite has a higher volatile content than anthracite. It is not as hard and ignites more easily. Otherwise, its properties are similar to those of anthracite.

Bituminous coal includes many types of coal with distinctly different compositions, properties, and burning characteristics. Coals range from high-grade bituminous, such as those found in the eastern United States, to low-rank coals, such as those found in the western United States. Caking properties range from coals that melt or become fully plastic, to those from which volatiles and tars are distilled without changing form (classed as noncaking or free-burning). Most bituminous coals are strong and nonfriable enough to allow screened sizes to be delivered free of fines. Generally, they ignite easily and burn freely. Flame length is long and varies with different coals. If improperly fired, much smoke and soot are possible, especially at low burning rates.

Semibituminous coal is soft and friable, and handling creates fines and dust. It ignites slowly and burns with a medium-length flame. Its caking properties increase as volatile matter increases, but the coke formed is weak. With only half the volatile matter content of bituminous coals, burning produces less smoke; hence, it is sometimes called smokeless coal.

Subbituminous coal, such as that found in the western United States, is high in moisture when mined and tends to break up as it dries or is exposed to the weather; it is likely to ignite spontaneously when piled or stored. It ignites easily and quickly, has a medium-length flame, and is noncaking and free-burning. The lumps tend to break into small pieces if poked. Very little smoke and soot are formed.

Lignite is woody in structure, very high in moisture when mined, of low heating value, and clean to handle. It has a greater tendency than subbituminous coals to disintegrate as it dries and is also more likely to ignite spontaneously. Because of its high moisture, freshly mined lignite ignites slowly and is noncaking. The char left after moisture and volatile matter are driven off burns very easily, like charcoal. The lumps tend to break up in the fuel bed and pieces of char that fall into the ash pit continue to burn. Very little smoke or soot forms.

Characteristics of Coal

The characteristics of coals that determine classification and suitability for given applications are the proportions of (1) volatile matter, (2) fixed carbon, (3) moisture, (4) sulfur, and (5) ash. Each of these is reported in the proximate analysis. Coal analyses can be reported on several bases: as-received, moisture-free (or dry), and mineral-matter-free (or ash-free). As-received is applicable for combustion calculations; moisture-free and mineral-matter-free, for classification purposes.

Volatile matter is driven off as gas or vapor when the coal is heated according to a standard temperature test. It consists of a variety of organic gases, generally resulting from distillation and decomposition. Volatile products given off by heated coals differ materially in the ratios (by mass) of the gases to oils and tars. No heavy oils or tars are given off by anthracite, and very small quantities are given off by semianthracite. As volatile matter increases to as much as 40% of the coal (dry and ash-free basis), increasing amounts of oils and tars are released. However, for coals of higher volatile content, the quantity of oils and tars decreases and is relatively low in the subbituminous coals and in lignite.

Fixed carbon is the combustible residue left after the volatile matter is driven off. It is not all carbon. Its form and hardness are an indication of fuel coking properties and, therefore, guide the choice of combustion equipment. Generally, fixed carbon represents that portion of fuel that must be burned in the solid state.

Moisture is difficult to determine accurately because a sample can lose moisture on exposure to the atmosphere, particularly when reducing the sample size for analysis. To correct for this loss, total

Licensed for single user. © 2021 ASHRAE, Inc.

Table 12 Typical Ultimate Analyses for Coals

Rank	As Received, MJ/kg	Constituents, Percent by Mass					
		O	H	C	N	S	Ash
Anthracite	29.5	5.0	2.9	80.0	0.9	0.7	10.5
Semianthracite	31.6	5.0	3.9	80.4	1.1	1.1	8.5
Low-volatile bituminous	33.4	5.0	4.7	81.7	1.4	1.2	6.0
Medium-volatile bituminous	32.6	5.0	5.0	81.4	1.4	1.5	6.0
High-volatile bituminous							
Type A	32.1	9.3	5.3	75.9	1.5	1.5	6.5
B	29.1	13.8	5.5	67.8	1.4	3.0	8.5
C	25.6	20.6	5.8	59.6	1.1	3.5	9.4
Subbituminous							
Type B	20.9	29.5	6.2	52.5	1.0	1.0	9.8
C	19.8	35.7	6.5	46.4	0.8	1.0	9.6
Lignite	16.0	44.0	6.9	40.1	0.7	1.0	7.3

moisture content of a sample is customarily determined by adding the moisture loss obtained when air-drying the sample to the measured moisture content of the dried sample. Moisture does not represent all of the water present in coal; water of decomposition (combined water) and of hydration are not given off under standardized test conditions.

Ash is the noncombustible residue remaining after complete coal combustion. Generally, the mass of ash is slightly less than that of mineral matter before burning.

Sulfur is an undesirable constituent in coal, because sulfur oxides formed when it burns contribute to air pollution and cause combustion system corrosion. Table 12 lists the sulfur content of typical coals. Legislation has limited the sulfur content of coals burned in certain locations.

Heating value may be reported on an as-received, dry, dry and mineral-matter-free, or moist and mineral-matter-free basis. Higher heating values of coals are frequently reported with their proximate analysis. When more specific data are lacking, the higher heating value of higher-quality coals can be calculated by the Dulong formula:

$$\text{Higher heating value, MJ/kg} = 33.829C + 144.28[H - (O/8)] + 9.42S \quad (4)$$

where C, H, O, and S are the mass fractions of carbon, hydrogen, oxygen, and sulfur in the coal obtained from the ultimate analysis.

Other important parameters in judging coal suitability include

- **Ultimate analysis**, which is another method of reporting coal composition. Percentages of C, H, O, N, S, and ash in the coal sample are reported. Ultimate analysis is used for detailed fuel studies and for computing a heat balance when required in heating device testing. Typical ultimate analyses of various coals are shown in Table 12.
- **Ash-fusion temperature**, which indicates the fluidity of the ash at elevated temperatures. It is helpful in selecting coal to be burned in a particular furnace and in estimating the possibility of ash handling and slagging problems.
- The **grindability index**, which indicates the ease with which a coal can be pulverized and is helpful in estimating ball mill capacity with various coals. There are two common methods for determining the index: Hardgrove (see Hardgrove Grindability Index at www.acarp.com.au/Media/ACARP-WP-5-HardgroveGrindabilityIndex.pdf) and ball mill.
- The **free-swelling index**, which denotes the extent of coal swelling on combustion on a fuel bed and indicates the coking characteristics of coal.

6. COMBUSTION CALCULATIONS

Calculations of the quantities of (1) air required for combustion and (2) flue gas products generated during combustion are frequently needed for sizing system components and as input to efficiency calculations. Other calculations, such as values for excess air and theoretical CO_2, are useful in estimating combustion system performance.

Frequently, combustion calculations can be simplified by using relative molecular mass. The relative molecular mass of a compound equals the sum of the atomic masses of the elements in the compound. Molecular mass can be expressed in any mass units. The gram molecular mass or gram mole is the molecular mass of the compound expressed in grams. The molecular mass of any substance contains the same number of molecules as the molecular mass of any other substance.

Corresponding to measurement standards common to the industries, calculations involving gaseous fuels are generally based on volume, and those involving liquid and solid fuels generally use mass.

Some calculations described here require data on concentrations of carbon dioxide, carbon monoxide, and oxygen in the flue gas. Gas analyses for CO_2, CO, and O_2 can be obtained by volumetric chemical analysis and other analytical techniques, including electromechanical cells used in portable electronic flue gas analyzers.

Air Required for Combustion

Stoichiometric (or theoretical) air is the exact quantity of air required to provide oxygen for complete combustion.

The three most prevalent components in hydrocarbon fuels (C, H_2, and S) are completely burned as in the following fundamental reactions:

$$C + O_2 \rightarrow CO_2$$
$$H_2 + 0.5O_2 \rightarrow H_2O$$
$$S + O_2 \rightarrow SO_2$$

In the reactions, C, H_2, and S can be taken to represent 1 kg mole of carbon, hydrogen, and sulfur, respectively. Using approximate atomic masses (C = 12, H = 1, S = 32, and O = 16), 12 kg of C are oxidized by 32 kg of O_2 to form 44 kg of CO_2, 2 kg of H_2 are oxidized by 16 kg of O_2 to form 18 kg of H_2O, and 32 kg of S are oxidized by 32 kg of O_2 to form 64 kg of SO_2. These relationships can be extended to include hydrocarbons.

The mass of dry air required to supply a given quantity of oxygen is 4.32 times the mass of the oxygen. The mass of air required to oxidize the fuel constituents listed in Table 1 was calculated on this basis. Deduct oxygen contained in the fuel, except the amount in ash, from the amount of oxygen required, because this oxygen is already combined with fuel components. In addition, when calculating the mass of supply air for combustion, allow for water vapor, which is always present in atmospheric air.

Combustion calculations for gaseous fuels are based on volume. **Avogadro's law** states that, for any gas, one mole occupies the same volume at a given temperature and pressure. Therefore, in reactions involving gaseous compounds, the gases react in volume ratios identical to the gram mole ratios. That is, to oxidize hydrogen in the preceding reaction, one volume (or 1 kg mole) of hydrogen reacts with one-half volume (or 0.5 kg mole) of oxygen to form one volume (or 1 kg mole) of water vapor.

The volume of air required to supply a given volume of oxygen is 4.78 times the volume of oxygen. The volumes of dry air required to oxidize the fuel constituents listed in Table 1 were calculated on this basis. Volume ratios are not given for fuels that do not exist in vapor form at reasonable temperatures or pressures. Again, oxygen contained in the fuel should be deducted from the quantity of oxygen required, because this oxygen is already combined with fuel

Licensed for single user. © 2021 ASHRAE, Inc.

components. Allow for water vapor, which increases the volume of dry air by 1 to 3%.

From the relationships just described, the theoretical mass m_a of dry air required for stoichiometric combustion of a unit mass of any hydrocarbon fuel is

$$m_a = 0.0144(8C + 24H + 3S - 3O) \quad (5)$$

where C, H, S, and O are the mass percentages of carbon, hydrogen, sulfur, and oxygen in the fuel.

Analyses of gaseous fuels are generally based on hydrocarbon components rather than elemental content.

If fuel analysis is based on mass, the theoretical mass m_a of dry air required for stoichiometric combustion of a unit mass of gaseous fuel is

$$m_a = 2.47CO + 34.28H_2 + 17.24CH_4 + 16.09C_2H_6 + 15.68C_3H_8 + 15.47C_4H_{10} + 13.27C_2H_2 + 14.78C_2H_4 + 6.08H_2S - 4.32O_2 \quad (6)$$

If fuel analysis is reported on a volumetric or molecular basis, it is simplest to calculate air requirements based on volume and, if necessary, convert to mass. The theoretical volume V_a of air required for stoichiometric combustion of a unit volume of gaseous fuels is

$$V_a = 2.39CO + 2.39H_2 + 9.57CH_4 + 16.75C_2H_6 + 23.95C_3H_8 + 31.14C_4H_{10} + 11.96C_2H_2 + 14.38C_2H_4 + 7.18H_2S - 4.78O_2 + 30.47 \text{ illuminants} \quad (7)$$

where CO, H_2, and so forth are the volumetric fractions of each constituent in the fuel gas.

Illuminants include a variety of compounds not separated by usual gas analysis. In addition to ethylene (C_2H_4) and acetylene (C_2H_2), the principal illuminants included in Equation (7), and the dry air required for combustion, per unit volume of each gas, are as follows: propylene (C_3H_6), 21.44; butylene (C_4H_8), 28.58; pentene (C_5H_{10}), 35.73; benzene (C_6H_6); 35.73, toluene (C_7H_8), 42.88; and xylene (C_8H_{10}), 50.02. Because toluene and xylene are normally scrubbed from the gas before distribution, they can be disregarded in computing air required for combustion of gaseous fuels. The percentage of illuminants present in gaseous fuels is small, so the values can be lumped together, and an approximate value of 30 unit volumes of dry air per unit volume of gas can be used. If ethylene and acetylene are included as illuminants, a value of 20 unit volumes of dry air per unit volume of gaseous illuminants can be used.

For many combustion calculations, only approximate values of air requirements are necessary. If approximate values for theoretical air are sufficient, or if complete information on the fuel is not available, the values in Tables 13 and 14 can be used. Another value used for estimating air requirements is 0.24 m^3 of air for 1 MJ of fuel.

In addition to the amount theoretically required for combustion, **excess air** must be supplied to most practical combustion systems to ensure complete combustion:

$$\text{Excess air, \%} = \frac{\text{Air supplied} - \text{Theoretical air}}{\text{Theoretical air}} \quad (8)$$

The excess air level at which a combustion process operates significantly affects its overall efficiency. Too much excess air dilutes flue gas excessively, lowering its heat transfer temperature and increasing sensible flue gas loss. Conversely, too little excess air can lead to incomplete combustion and loss of unburned combustible gases. Combustion efficiency is usually maximized when just enough excess air is supplied and properly mixed with combustible gases to ensure complete combustion. The general practice is to supply 5 to 50% excess air, depending on the type of fuel burned, combustion equipment, and other factors.

Table 13 Approximate Air Requirements for Stoichiometric Combustion of Fuels by Category

Type of Fuel	Air Required		Approx. Precision, %	Exceptions
	kg/kg Fuel	m^3/Unit Fuel*		
Solid	MJ/kg × 0.314	MJ/kg × 0.26	3	Fuels containing more than 30% water
Liquid	MJ/kg × 0.305	MJ/kg × 0.35	3	Results low for gasoline and kerosene
Gas	MJ/kg × 0.288	MJ/m^3 × 0.24	5	11.2 MJ/m^3 or less

Source: Data based on Shnidman (1954).
*Unit fuel for solid and liquid fuels in kg, for gas in L.

Table 14 Theoretical Air Requirements for Stoichiometric Combustion of Various Fuels

Type of Fuel	Theoretical Air Required for Combustion
Solid fuels	kg/kg fuel
Anthracite	9.6
Semibituminous	11.2
Bituminous	10.3
Lignite	6.2
Coke	11.2
Liquid fuels	Mg/m^3 fuel
No. 1 fuel oil	12.34
No. 2 fuel oil	12.70
No. 5 fuel oil	13.42
No. 6 fuel oil	13.66
Gaseous fuels	m^3/m^3 fuel
Natural gas	9.6
Butane	31.1
Propane	24.0

The amount of dry air supplied per unit mass of fuel burned can be obtained from the following equation, which is reasonably precise for most solid and liquid fuels:

$$\text{Dry air supplied} = \frac{C(3.04N_2)}{CO_2 + CO} \quad (9)$$

where

Dry air supplied = unit mass per unit mass of fuel
C = unit mass of carbon burned per unit mass of fuel, corrected for carbon in ash
CO_2, CO, N_2 = percentages by volume from flue gas analysis

These values of dry air supplied and theoretical air can be used in Equation (8) to determine excess air.

Excess air can also be calculated from unit volumes of stoichiometric combustion products and air, and from volumetric analysis of the flue gas:

$$\text{Excess air, \%} = 100\left(\frac{P}{A}\right)\left(\frac{U - CO_2}{CO_2}\right) \quad (10)$$

where

U = ultimate carbon dioxide of flue gases resulting from stoichiometric combustion, %
CO_2 = carbon dioxide content of flue gases, %
P = dry products from stoichiometric combustion, unit volume per unit volume of gas burned
A = air required for stoichiometric combustion, unit volume per unit volume of gas burned

Because the ratio P/A is approximately 0.9 for most natural gases, a value of 90 can be substituted for $100(P/A)$ in Equation (10) for rough calculation.

Table 15 Approximate Maximum Theoretical (Stoichiometric) CO_2 Values, and CO_2 Values of Various Fuels with Different Percentages of Excess Air

Type of Fuel	Theoretical or Maximum CO_2, %	Percent CO_2 at Given Excess Air Values		
		20%	40%	60%
Gaseous fuels				
Natural gas	12.1	9.9	8.4	7.3
Propane gas (commercial)	13.9	11.4	9.6	8.4
Butane gas (commercial)	14.1	11.6	9.8	8.5
Mixed gas (natural and carbureted water gas)	11.2	12.5	10.5	9.1
Carbureted water gas	17.2	14.2	12.1	10.6
Coke oven gas	11.2	9.2	7.8	6.8
Liquid fuels				
No. 1 and 2 fuel oil	15.0	12.3	10.5	9.1
No. 6 fuel oil	16.5	13.6	11.6	10.1
Solid fuels				
Bituminous coal	18.2	15.1	12.9	11.3
Anthracite	20.2	16.8	14.4	12.6
Coke	21.0	17.5	15.0	13.0

Because excess air calculations are almost invariably made from flue gas analysis results and theoretical air requirements are not always known, another convenient method of expressing Equation (8) is

$$\text{Excess air, \%} = \frac{100[O_2 - (CO/2)]}{0.264N_2 - [O_2 - (CO/2)]} \quad (11)$$

(12)

where O_2, CO, and N_2 are percentages by volume from the flue gas analysis, dry basis.

Theoretical CO_2

The theoretical (or ultimate, stoichiometric, or maximum) CO_2 concentration attainable in the products from the combustion of a hydrocarbon fuel with air is obtained when the fuel is completely burned with the theoretical quantity of air and zero excess air. Theoretical CO_2 varies with the carbon/hydrogen ratio of the fuel. For combustion with excess air present, theoretical CO_2 values can be calculated from the flue gas analysis:

$$\text{Theoretical } CO_2, \% = U = \frac{CO_2}{1 - (O_2/20.95)} \quad (12)$$

where CO_2 and O_2 are percentages by volume from the flue gas analysis, dry basis.

Table 15 gives approximate theoretical CO_2 values for stoichiometric combustion of several common types of fuel, as well as CO_2 values attained with different amounts of excess air. In practice, desirable CO_2 values depend on the excess air, fuel, firing method, and other considerations.

Quantity of Flue Gas Produced

The mass of dry flue gas produced per mass of fuel burned is required in heat loss and efficiency calculations. This mass is equal to the sum of the mass of (1) fuel (minus ash retained in the furnace), (2) air theoretically required for combustion, and (3) excess air. For solid fuels, this mass, determined from the flue gas analysis, is

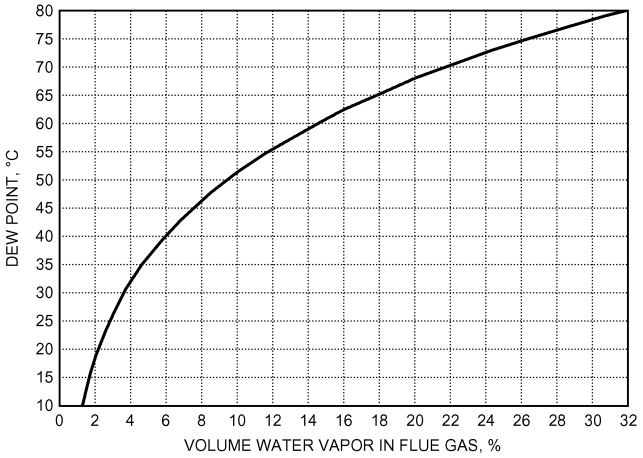

Fig. 3 Water Vapor and Dew Point of Flue Gas
Adapted from *Gas Engineers Handbook* (1965). Printed with permission of Industrial Press and American Gas Association.

$$\text{Dry flue gas} = \frac{11CO_2 + 8O_2 + 7(CO + N_2)}{3(CO_2 + CO)} \quad (13)$$

where

Dry flue gas = kg/kg of fuel
C = kg of carbon burned per kg of fuel, corrected for carbon in ash
CO_2, O_2, CO, N_2 = percentages by volume from flue gas analysis

The total dry gas volume of flue gases from combustion of one unit volume of gaseous fuels for various percentages of CO_2 is

$$\text{Dry flue gas} = \left(\frac{\text{Volume of } CO_2 \text{ produced}}{\text{Unit vol. of gas burned}}\right)\left(\frac{100}{CO_2}\right) \quad (14)$$

where

Dry flue gas = unit volume per unit volume of gaseous fuel
CO_2 = percentage by volume from the flue gas analysis

Excess air quantity can be estimated by subtracting the quantity of dry flue gases resulting from stoichiometric combustion from the total volume of flue gas.

Water Vapor and Dew Point of Flue Gas

Water vapor in flue gas is the total of the water (1) contained in the fuel, (2) contained in the stoichiometric and excess air, and (3) produced from combustion of hydrogen or hydrocarbons in the fuel. The amount of water vapor in stoichiometric combustion products may be calculated from the fuel burned by using the water data in Table 1.

The dew point is the temperature at which condensation begins and can be determined using Figure 3. The volume fraction of water vapor P_{wv} in the flue gas can be determined as follows:

$$P_{wv} = \frac{V_w}{(100V_c/P_c) + V_w} \quad (15)$$

where

V_w = total water vapor volume (from fuel; stoichiometric, excess, and dilution air; and combustion)
V_c = unit volume of CO_2 produced per unit volume of gaseous fuel
P_c = percent CO_2 in flue gas

Using Figure 4, the dew points of solid, liquid, or gaseous fuels may be estimated. For example, to find the dew point of flue gas resulting from the combustion of a solid fuel with a mass ratio

Licensed for single user. © 2021 ASHRAE, Inc.

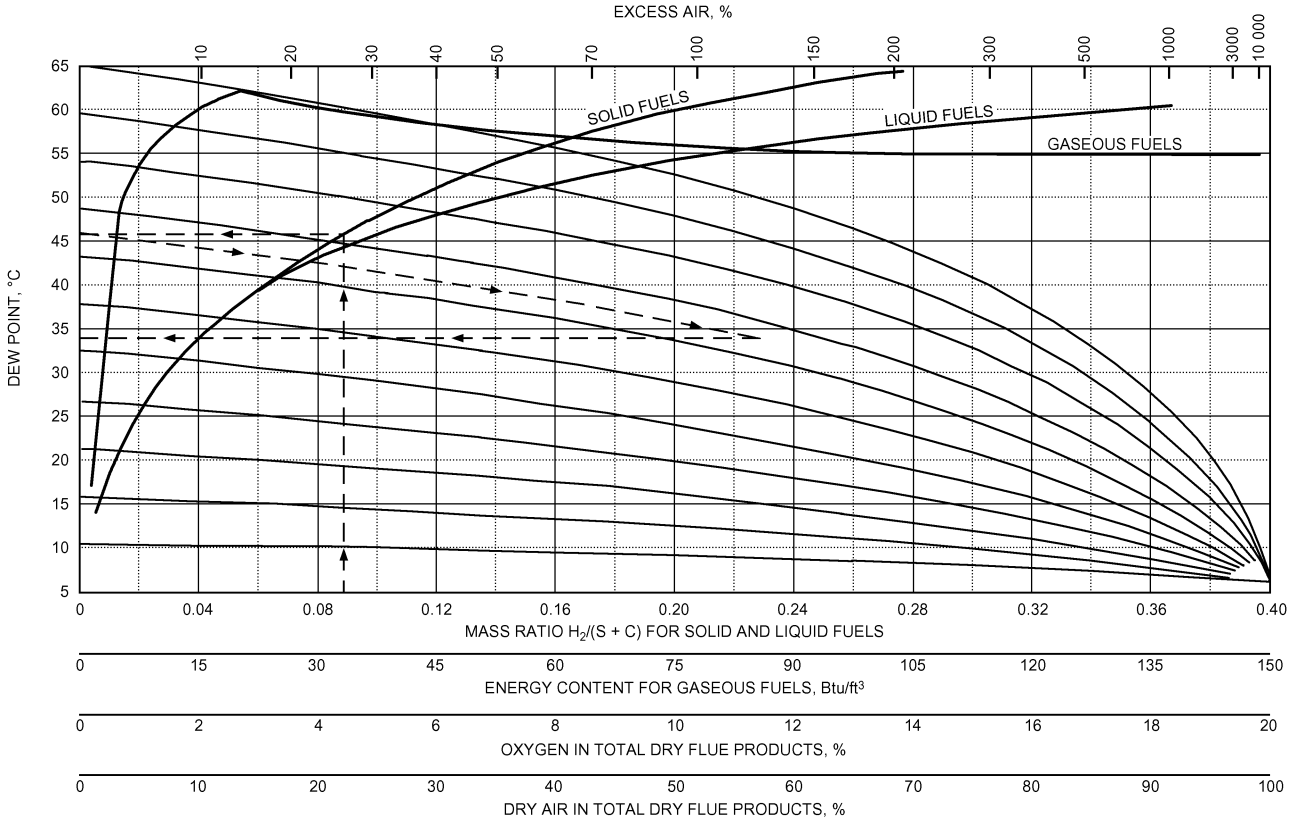

Fig. 4 Theoretical Dew Points of Combustion Products of Industrial Fuels
Adapted from *Gas Engineers Handbook* (1965). Printed with permission of Industrial Press and American Gas Association.

(hydrogen to carbon-plus-sulfur) of 0.088 and sufficient excess air to produce 11.4% oxygen in the flue gas, start with the mass ratio of 0.088. Proceed vertically to the intersection of the solid fuels curve and then to the theoretical dew point of 46°C on the dew-point scale (see dashed lines in Figure 4). Follow the curve fixed by this point (down and to the right) to 11.4% oxygen in the flue gas (on the abscissa). The actual dew point is 34°C and is found on the dew-point scale.

The dew point can be estimated for flue gas from natural gas having a higher heating value (HHV) of 38 MJ/m^3 with 6.3% oxygen or 31.5% air. Start with 38 MJ/m^3 and proceed vertically to the intersection of the gaseous fuels curve and then to the theoretical dew point of 59°C on the dew-point scale. Follow the curve fixed by this point to 6.3% oxygen or 31.5% air in the flue gas. The actual dew point is 53°C.

The presence of sulfur dioxide, and particularly sulfur trioxide, influences the vapor pressure of condensate in flue gas, and the dew point can be raised by as much as 14 to 42°C, as shown in Figure 5. For a manufactured gas with an HHV of 20.5 MJ/m^3 containing 340 mg of sulfur per cubic metre being burned with 40% excess air, the proper curve in Figure 5 is determined as follows:

$$\frac{\text{Mass sulfur in fuel, mg/m}^3}{\text{Fuel heating value, MJ/m}^3} = \frac{340}{20.5} = 16.6 \qquad (16)$$

This curve lies between the 0 and 20 curves and is close to the 20 curve. The dew point for any percentage of excess air from zero to 100% can be determined on this curve. For this flue gas with 40% excess air, the dew point is about 80°C, instead of 65°C for zero sulfur at 40% excess air.

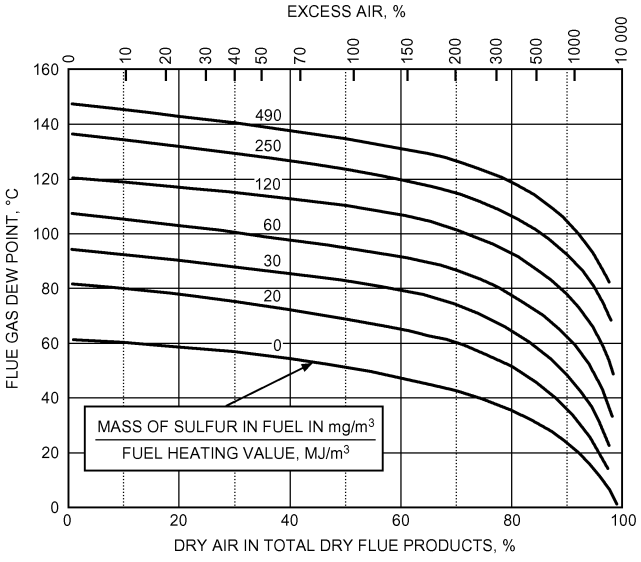

Fig. 5 Influence of Sulfur Oxides on Flue Gas Dew Point

Sample Combustion Calculations

Example 2. Analysis of flue gases from burning a natural gas shows 10.0% CO_2, 3.1% O_2, and 86.9% N_2 by volume. Analysis of the fuel is 90%

Licensed for single user. © 2021 ASHRAE, Inc.

CH_4, 5% N_2, and 5% C_2H_6 by volume. Find U (maximum theoretical percent CO_2), and percentage of excess air.

Solution: From Equation (12),

$$U = \frac{10.0}{1 - (3.1/20.95)} = 11.74\%\ CO_2$$

From Equation (10), using $100(P/A) = 90$,

$$\text{Excess air} = \frac{(11.74 - 10.0)90}{10} = 15.7\%$$

Example 3. For the same analysis as in Example 2, find, per cubic metre of fuel gas, the volume of dry air required for combustion, the volume of each constituent in the flue gases, and the total volume of dry and wet flue gases.

Solution: From Equation (7), the volume of dry air required for combustion is

$$9.57CH_4 + 16.75C_2H_6 = (9.57 \times 0.90) + (16.75 \times 0.05)$$
$$= 9.45\ m^3 \text{ per } m^3 \text{ of fuel gas}$$

(The volume of dry air may also be calculated using Table 14.)

From Table 1, the cubic metres of flue gas constituents per cubic metre of fuel gas are as follows:

Nitrogen, N_2

From methane	$(0.9CH_4)(9.57 - 2.0)$	= 6.81
From ethane	$(0.05C_2H_6)(16.75 - 3.5)$	= 0.66
Nitrogen in fuel		= 0.05
Nitrogen in excess air	$0.791 \times 0.157 \times 9.45$	= 1.17
	Total nitrogen	= 8.69 m^3

Oxygen, O_2

In excess air	$0.209 \times 0.157 \times 9.45$	= 0.31 m^3

Carbon dioxide, CO_2

From methane	$(0.9CH_4)(1.0)$	= 0.90
From ethane	$(0.05C_2H_6)(2.0)$	= 0.10
	Total carbon dioxide	= 1.00 m^3

Water vapor, H_2O (does not appear in some flue gas analyses)

From methane	$(0.9CH_4)(2.0)$	= 1.8
From ethane	$(0.05C_2H_6)(3.0)$	= 0.15
	Total water vapor	= 1.95 m^3

Total volume of dry gas per cubic metre of fuel gas

$$8.69 + 0.31 + 1.00 = 10.0\ m^3$$

Total volume of wet gases per cubic metre of fuel gas (neglecting water vapor in combustion air)

$$10.0 + 1.95 = 11.95\ m^3$$

The cubic metres of dry flue gas per cubic metre of fuel gas can also be computed from Equation (14):

$$(1.00)(100)/10.0 = 10.0\ m^3$$

7. EFFICIENCY CALCULATIONS

In analyzing heating appliance efficiency, an energy balance is made that accounts (as much as possible) for disposition of all thermal energy released by combustion of the fuel quantity consumed. The various components of this balance are generally expressed in terms of megajoules per kilogram of fuel burned or as a percentage of its higher heating value. The following are major components of an energy balance and their calculation methods:

1. Useful heat q_1, or heat transferred to the heated medium; for convection heating equipment, this value is computed as the product of the mass rate of flow and enthalpy change.
2. Heat loss as sensible heat in the dry flue gases

$$q_2 = m_g c_{pg}(t_g - t_a) \quad (17)$$

where m_g (mass of dry flue gas per mass of fuel, kg/kg) is calculated as in Equation (13).

3. Heat loss in water vapor in products formed by combustion of hydrogen

$$q_3 = (9H_2/100)[(h)_{tg} - (h_f)_{ta}] \quad (18)$$

4. Heat loss in water vapor in the combustion air

$$q_4 = Mm_a[(h)_{tg} - (h_g)_{ta}] \quad (19)$$

where m_a is calculated as in Equations (5) and (6).

5. Heat loss from incomplete combustion of carbon

$$q_5 = 23\ 591\,C\left(\frac{CO}{CO_2 + CO}\right) \quad (20)$$

6. Heat loss from unburned carbon in the ash or refuse

$$q_6 = 33\ 957[(C_u/100) - C] \quad (21)$$

7. Unaccounted-for heat losses, q_7

The following symbols are used in Equations (17) to (21):

q_1 = useful heat, kJ/kg of fuel
q_2 = heat loss in dry flue gases, kJ/kg of fuel
q_3 = heat loss in water vapor from combustion of hydrogen, kJ/kg of fuel
q_4 = heat loss in water vapor in combustion air, kJ/kg of fuel
q_5 = heat loss from incomplete combustion of carbon, kJ/kg of fuel
q_6 = heat loss from unburned carbon in ash, kJ/kg of fuel
q_7 = unaccounted-for heat losses, kJ/kg of fuel
c_{pg} = mean specific heat of flue gases at constant pressure [from 1.01 to 1.06 kJ/(kg·K) for flue gas temperatures from 150 to 540°C], kJ/(kg·K)
$(h)_{tg}$ = enthalpy of superheated steam at flue gas temperature and 101.4 kPa, kJ/kg
$(h_f)_{ta}$ = enthalpy of saturated water liquid at air temperature, kJ/kg
$(h_g)_{ta}$ = enthalpy of saturated steam at combustion air temperature, kJ/kg
m_a = mass of combustion air per mass of fuel used, kg/kg of fuel
m_g = mass of dry flue gas per mass of fuel, kg/kg of fuel
t_a = temperature of combustion air, °C
t_g = temperature of flue gases at exit of heating device, °C
H_2 = hydrogen in fuel, % by mass (from ultimate analysis of fuel)
M = humidity ratio of combustion air, mass of water vapor per mass of dry air
CO, CO_2 = carbon monoxide and carbon dioxide in flue gases, % by volume
C = mass of carbon burned per unit of mass of fuel, corrected for carbon in ash, kg/kg of fuel

$$C = \frac{WC_u - W_a C_a}{100W} \quad (22)$$

where

C_u = percentage of carbon in fuel by mass from ultimate analysis
W_a = mass of ash and refuse
C_a = percent of combustible in ash by mass (combustible in ash is usually considered to be carbon)
W = mass of fuel used

Useful heat (item 1) is generally measured for a particular piece of combustion equipment.

Flue gas loss is the sum of items 2 to 6. However, for clean-burning gas- and oil-fired equipment, items 5 and 6 are usually negligible and flue gas loss is the sum of items 2, 3, and 4.

Flue gas losses (the sum of items 2, 3, and 4) can be determined with sufficient precision for most purposes from the curves in Figure 6, if O_2 content and flue gas temperature are known. Values

Licensed for single user. © 2021 ASHRAE, Inc.

of the losses were computed from typical ultimate analyses, assuming 1% water vapor (by mass) in the combustion air. Curves for medium-volatile bituminous coal can be used for high-volatile bituminous coal with no appreciable error.

Generally, item 5 is negligible for modern combustion equipment in good operating condition.

Item 6 is generally negligible for gas and oil firing, but should be determined for coal-firing applications.

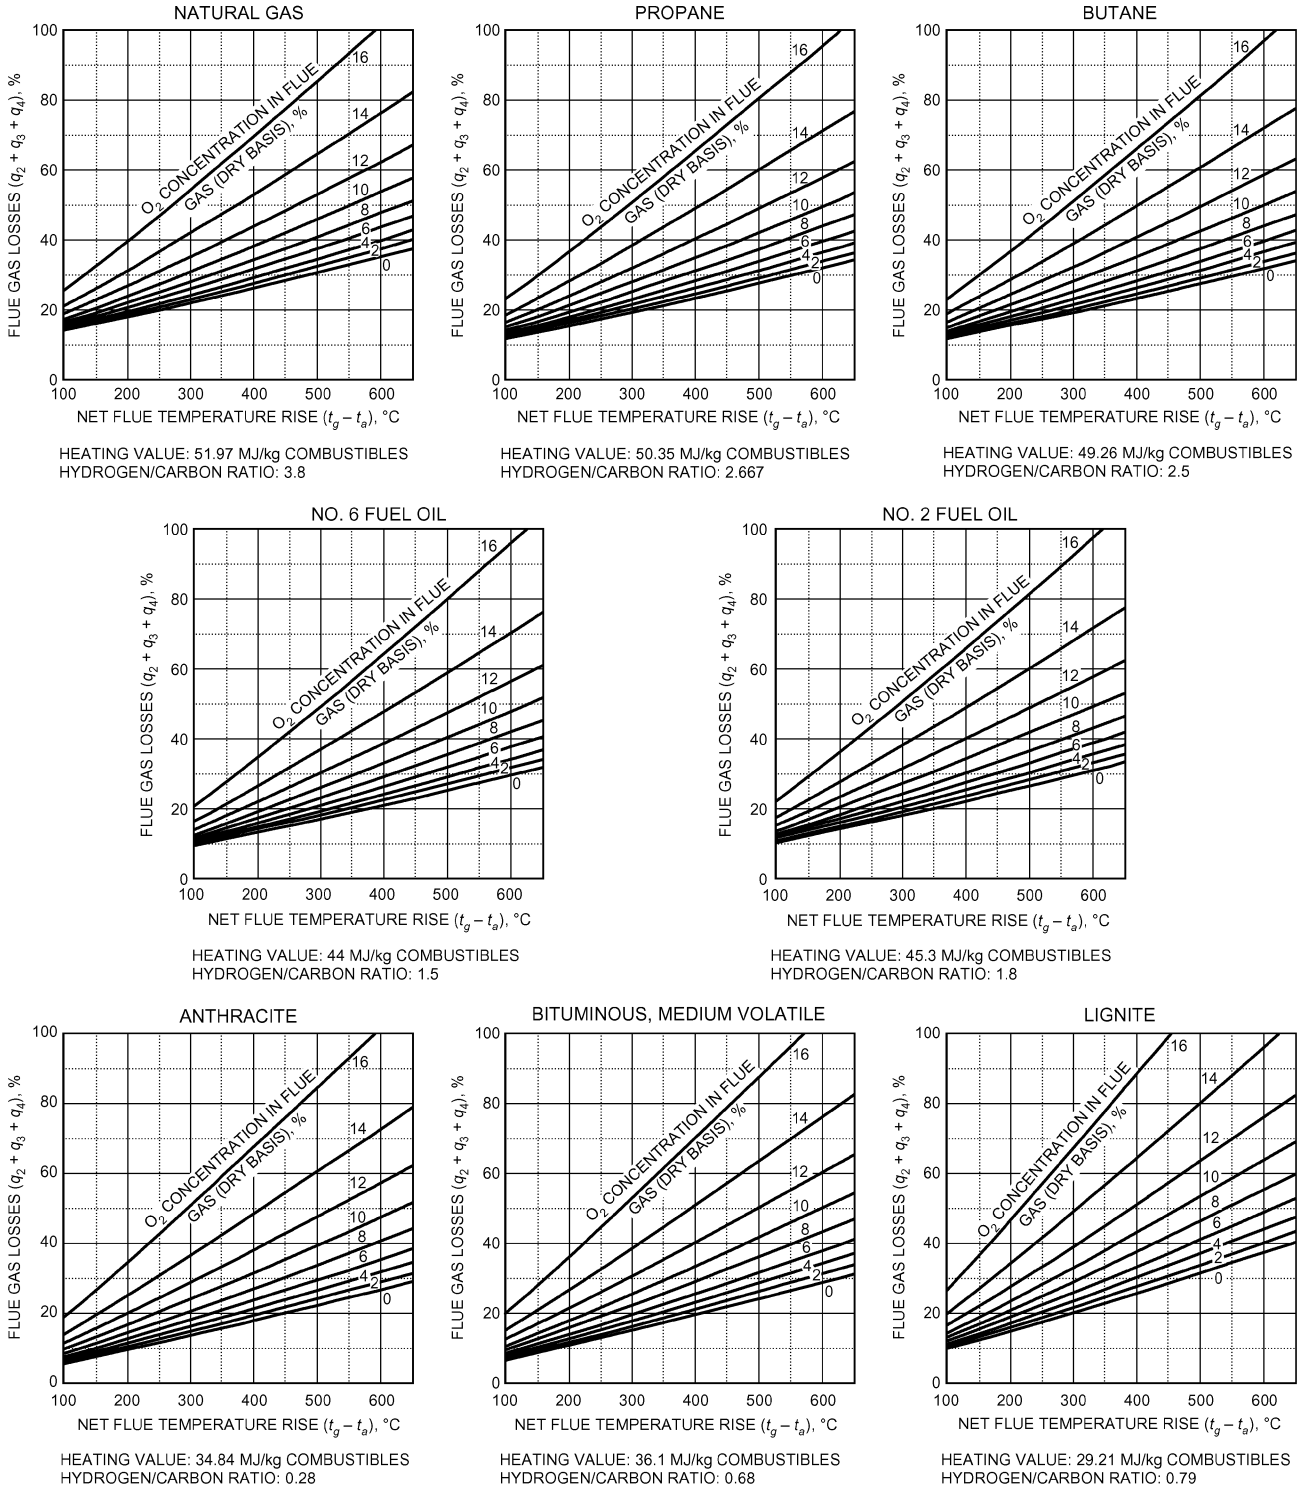

Fig. 6 Flue Gas Losses with Various Fuels
(Flue gas temperature rise shown. Loss based on 18°C room temperature.)

Licensed for single user. © 2021 ASHRAE, Inc.

Item 7 consists primarily of radiation and convection losses from combustion equipment surfaces and losses caused by incomplete combustion not included in items 5 and 6. Heat loss from incomplete combustion is determined by subtracting the sum of items 1 to 6 from the fuel heating value.

Radiation and convection losses are not usually determined by direct measurement, but if the heating appliance is located within the heated space, radiation and convection losses can be considered useful heat rather than lost heat and can be omitted from heat loss calculations or added to item 1.

If CO is present in flue gases, small amounts of unburned hydrogen and hydrocarbons may also be present. The small losses caused by incomplete combustion of these gases would be included in item 7, if item 7 was determined by subtracting items 1 to 6 from the fuel heating value.

The overall thermal efficiency of combustion equipment is defined as

$$\text{Thermal efficiency, \%} = 100 \times \frac{\text{Useful heat}}{\text{Heating value of fuel}} \tag{23}$$

Equation (24) can be used to estimate efficiency for equipment where item 7 is small or radiation and convection are useful heat:

$$\text{Thermal efficiency, \%} = 100 \times \frac{\text{Heating value of fuel} - (q_2 + q_3 + q_4 + q_5 + q_6)}{\text{Heating value of fuel}} \tag{24}$$

Using heating values based on gas volume, a gas appliance's thermal efficiency can be computed with sufficient precision by the following equation:

$$\eta = \frac{100(Q_h - Q_{fl})}{Q_h} \tag{25}$$

where

η = thermal efficiency, %
Q_h = higher heating value of fuel gas per unit volume
Q_{fl} = flue gas losses per unit volume of fuel gas

To produce heat efficiently by burning any common fuel, flue gas losses must be minimized by (1) providing adequate heat-absorbing surface in the appliance, (2) keeping heat transfer surfaces clean on both fire and water or air sides, and (3) reducing excess air to the minimum level consistent with complete combustion and discharge of combustion products.

Seasonal Efficiency

The method just presented is useful for calculating the steady-state efficiency of a heating system or device. Unfortunately, the seasonal efficiency can be significantly different from the steady-state efficiency. The primary factor affecting seasonal efficiency is flue loss during the burner-off period. The warm stack that exists at the end of the firing period can cause airflow in the stack while the burner is off, which can remove heat from furnace and heat exchanger components, the structure itself, and pilot flames. Also, if combustion air is drawn from the heated space within the structure, the heated air lost must be at least partly replaced with cold infiltrated air. For further discussion of seasonal efficiency, see Chapters 10 and 33 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment* and Chapter 19 of this volume.

Table 16 NO_x Emission Factors for Combustion Sources

Source	NO_x Emission Factor, mg/MJ of Heat Input	
	Without Emission Controls	With Emission Controls
Gas-fired equipment		
Small industrial boilers	60	9
Commercial boilers	43	9
Residential furnaces	39	14
Distillate-oil-fired small industrial boilers, commercial boilers, and residential furnaces	60	
Residual-oil-fired small industrial boilers and commercial boilers	160	

8. COMBUSTION CONSIDERATIONS

Air Pollution

Combustion processes constitute the largest single source of anthropogenic (human-caused) air pollution. Pollutants can be grouped into five categories:

- Products of incomplete fuel combustion
  - Combustible aerosols (solid and liquid), including smoke, soot, and organics, but excluding ash
  - Carbon monoxide CO
  - Gaseous hydrocarbons
- Carbon dioxide CO_2
- Oxides of nitrogen (collectively referred to as NO_x)
  - Nitric oxide NO
  - Nitrogen dioxide NO_2
- Emissions resulting from fuel contaminants
  - Sulfur oxides, primarily sulfur dioxide SO_2 and small quantities of sulfur trioxide SO_3
  - Ash
  - Trace metals
- Emissions resulting from additives
  - Combustion-controlling additives
  - Mercaptans
  - Other additives

Emission levels of nitrogen oxides and products of incomplete combustion are directly related to the combustion process and can be controlled, to some extent, by process modification. Emissions from fuel contaminants are related to fuel selection and are slightly affected by the combustion process. Emissions from additives must be considered in the overall evaluation of the merits of using additives.

Carbon dioxide as a pollutant has gained attention because of its suspected effect on global warming. Carbon dioxide is produced by HVAC&R equipment (either directly or as a result of generating the electric power to operate the HVAC&R equipment), transportation, industry, and other sources. Carbon dioxide emissions can be minimized by increasing appliance operating efficiencies and using fuels with higher hydrogen content.

Nitrogen oxides are produced during combustion, either (1) by thermal fixation (reaction of nitrogen and oxygen at high combustion temperatures), or (2) from fuel nitrogen (oxidation of organic nitrogen in fuel molecules). Unfortunately, high excess air and high flame temperature techniques, which ensure complete fuel combustion, tend to promote NO_x formation. NO levels in flames where the reactants are premixed tend to peak with excess air levels around 10%. Higher excess air levels generally reduce the amount of NO_x and flame temperatures.

Licensed for single user. © 2021 ASHRAE, Inc.

Table 16 lists some NO_x emission factors for fuel-burning equipment. Differences in emissions are caused by flame temperature and different levels of fuel nitrogen. Carbon monoxide emissions depend less on fuel type and typically range from 13 to 17 mg/MJ of heat input. For gas-fired commercial and industrial boilers, particulate emissions range from 2.2 to 2.6 mg/MJ. For distillate-oil-fired commercial and industrial boilers, particulates are typically 6.0 mg/MJ. For residential oil-fired equipment, particulate emission factors are 1.3 mg/MJ. For residual-oil-fired equipment, particulate emissions depend on the sulfur content and, to a lesser extent, the mineral content. For a sulfur content of 1%, the particulate emission rate is typically 36 mg/MJ.

Emission levels of products of incomplete fuel combustion can be reduced by reducing burner cycling, ensuring adequate excess air, improving mixing of air and fuel (by increasing turbulence, improving distribution, and improving liquid fuel atomization), increasing residence time in the hot combustion zone (possibly by decreasing the firing rate), increasing combustion zone temperatures (to speed reactions), and avoiding quenching the flame before reactions are completed.

Relative humidity of combustion air affects the amount of NO_x produced and must be considered when specifying acceptable NO_x emission rates and measuring NO_x production during appliance tests.

The relative contribution of each of these mechanisms to the total NO_x emissions depends on the amount of organic nitrogen in the fuel. Natural gas normally contains very little nitrogen. Virtually all NO_x emissions with gas firing are due to the thermal mechanism. Nitrogen content of distillate oil varies, but an average of 20 ppm of fuel NO_x is produced (about 20 to 30% of the total NO_x). Levels in residual oil can be significantly higher, with fuel NO_x contributing heavily to the total emissions.

Thermal fixation depends strongly on flame maximum temperature. For example, increasing the flame temperature from 1400 to 1500°C increases thermal NO_x tenfold. Therefore, methods to control thermal NO_x are based on methods to reduce the maximum flame temperature. Flue gas recirculation is perhaps the most effective method for commercial and industrial boilers. In gas-fired boilers, NO_x can be reduced 70% with 15 to 20% recirculation of flue gas into the flame. The NO_x reduction decreases with increasing fuel nitrogen content. With distillate-oil firing, reductions of 60 to 70% can be achieved. In residual-oil-fired boilers, flue gas recirculation can reduce NO_x emissions by 15 to 30%. The maximum rate of flue gas recirculation is limited by combustion instability and CO production.

Two-stage firing is the only technique that reduces NO_x produced both by thermal fixation and fuel nitrogen in industrial and utility applications. The fuel-rich or air-deficient primary combustion zone retards NO_x formation early in combustion (when NO_x forms most readily from fuel nitrogen), and avoids peak temperatures, reducing thermal NO_x. Retrofit low-NO_x burners that control air distribution and fuel air mixing in the flame zone can be used to achieve staged combustion. With oil firing, NO_x reductions of 20 to 50% can be obtained with low-NO_x burners. Application of flue gas recirculation and other control methods to residential, oil-fired heating systems was reviewed by Butcher et al. (1994).

The following are some methods of reducing NO_x emissions from gas-fired appliances (Murphy and Putnam 1985):

- Total premix
- Burner adjustment
- Flame inserts (radiation screens or rods)
- Staged combustion and delayed mixing
- Secondary air baffling
- Catalytic and radiant burners
- Pulse

Radiation screens or rods (flame inserts) surrounding or inserted into the flame absorb radiation to reduce flame temperature and retard NO_x formation. Proprietary appliance burners with no flame inserts have been produced to comply with the very strict NO_x emission limitations of California's Air Quality Management Districts.

The U.S. EPA sets limits on air pollutant emissions (Source Performance Standards) from boilers larger than 3 MW of heat input. In addition, states set emission regulations that are at least as strict at the federal limits and may apply to smaller equipment.

The EPA's automobile emission standard is 0.62 g of NO_2 per kilometre, which is equivalent to 750 ng/J of NO_x emission. California's maximum is 0.25 g/km, equivalent to 300 ng/J. California's Air Quality Management Districts for the South Coast (Los Angeles) and the San Francisco Bay Area limit NO_x emission to 14 ng/J of useful heat for some natural gas-fired central furnaces.

For further discussion of air pollution aspects of fuel combustion, see EPA (1971a, 1971b).

Portable Combustion Analyzers (PCAs)

These battery-powered electronic instruments, also known as flue gas analyzers (FGAs), have been widely used for over 30 years. Their sensors measure various gases found in flues of combustion appliances, whether fired by gas, oil, or solid fuels.

Users place the analyzer's probe in the flue of an appliance to extract combustion gases for measurement. These gases pass through a water trap to create a dry gas for measurement, and then have excess particles removed by a filter before entering the PCA with help from its internal pump.

The PCA's sensors measure or calculate real-time readings of oxygen (O_2), carbon monoxide (CO), and carbon dioxide (CO_2). Most PCAs also measure temperature, pressure, and draft; some measure the ratio of CO to CO_2, detect gas leaks, or measure other gases such as nitric oxide (NO), nitrogen dioxide (NO_2), sulfur dioxide (SO_2), and hydrocarbons (CH_4) and transfer test results to a printer, PC, smartphone, or tablet. If in doubt, ask the manufacturer which model is appropriate for a specific application.

Pay particular attention to the user manual's care instructions. These include switching on in outdoor air to allow sensors to tare (zero out) correctly, not leaving a PCA overnight in a cold vehicle, and ensuring the PCA is annually recertified by an authorized service provider to keep its metrological performance within specification.

An annual calibration certificate is essential. As a minimum, it should include

- PCA serial number and type
- Calibration date
- Next calibration due date or certificate expiration date
- Reference to test gases and instruments used during calibration process
- Ambient conditions at time of test
- Calibration results of parameters calibrated
- Uncertainty measurement

All calibrated PCAs should have a label or sticker applied including the name of the company who performed the work and the PCA's next service date. The label should reference the PCA using a serial number or certificate number, be tamperproof, and be placed where it can easily be seen. PCAs generally rely on service software, usually only available from the manufacturer or an approved service center. Using nonauthorized companies may invalidate the PCA's warranty and may lead to incorrect replacement parts being used.

An American PCA performance standard, AHRI *Standard* 1260P, is in development, but most PCAs are already certified to European Standard CEN *Standard* 50379, which has three parts:

Licensed for single user. © 2021 ASHRAE, Inc.

- Part 1 defines general requirements of and test methods for PCAs
- Part 2 defines PCA performance requirements where statutory inspections are required
- Part 3 defines PCA performance requirements where nonstatutory inspections are required (e.g., in most European countries other than Germany and Austria)

CEN *Standard* 50379 defines which gases are included (CO, NO, SO_2, O_2, and CO_2 if fitted to the PCA) and what accuracy, response, and performance criteria PCAs must meet. The standard also tests for sensor cross sensitivity, long life, drop, and vibration to ensure reliability in normal applications under competent use. Some PCAs are used to measure ambient levels of CO and CO_2 in residential or commercial environments. In Europe, these PCAs must meet the performance requirements of CEN *Standard* 50543; some PCAs are already certified to this standard as well as to CEN *Standard* 50379.

Condensation and Corrosion

Fuel-burning systems that cycle on and off to meet demand cool down during the *off* cycle. When the appliance starts again, condensate forms briefly on surfaces until they are heated above the dew-point temperature. Low-temperature corrosion occurs in system components (heat exchangers, flues, vents, chimneys) when their surfaces remain below the dew-point temperature of flue gas constituents (water vapor, sulfides, chlorides, fluorides, etc.) long enough to cause condensation. Corrosion increases as condensate dwell time increases.

Acids in flue gas condensate are the principal substances responsible for low-temperature corrosion in fuel-fired systems. Sulfuric, hydrochloric, and other acids are formed when acidic compounds in fuel and air combustion products combine with condensed moisture in appliance heat exchangers, flues, or vents. Corrosion can be avoided by maintaining these surfaces above the flue gas dew point.

In high-efficiency, condensing-type appliances and economizers, flue gas temperatures are intentionally reduced below the flue gas dew-point temperatures to achieve efficiencies approaching 100%. In these systems, surfaces subjected to condensate must be made of corrosion-resistant materials. The most corrosive conditions exist at the leading edge of the condensing region, especially areas that experience evaporation during each cycle (Stickford et al. 1988). Draining condensate retards the concentration of acids on system surfaces; regions from which condensate partially or completely drains away before evaporation are less severely attacked than regions from which condensate does not drain before evaporation.

The metals most resistant to condensate corrosion are stainless-steel alloys with high chromium and molybdenum content, and nickel-chromium alloys with high molybdenum content (Stickford et al. 1988). Aluminum experiences general corrosion rather than pitting when exposed to flue gas condensate. If applied in sufficiently thick cross section to allow for metal loss, aluminum can be used in condensing regions. Most ceramic and high-temperature polymer materials resist the corrosive effects of flue gas condensate. These materials may have application in the condensing regions, if they can meet the structural and temperature requirements of a particular application.

In coal-fired power plants, the rate of corrosion for carbon steel condensing surfaces by mixed acids (primarily sulfuric and hydrochloric) is reported to be maximum at about 50°C ± 10 K (Davis 1987). Mitigation techniques include (1) acid neutralization with a base such as NH_3 or $Ca(OH)_2$; (2) use of protective linings of glass-filled polyester or coal-tar epoxy; and (3) replacing steel with molybdenum-bearing stainless steels, nickel alloys, polymers, or other corrosion-resistant materials. Other elements in residual fuel oils and coals that contribute to high-temperature corrosion include sodium, potassium, and vanadium. Each fuel-burning system component should be evaluated during installation, or when modified, to determine the potential for corrosion and the means to retard corrosion (Paul et al. 1988).

If fuel-burning appliances accumulate condensate that does not evaporate, the condensate must be routed into a trapped drainage system. Because the condensate may be acidic, the drainage system must be suitable and environmentally acceptable. Condensate freezing must be considered in cold climates.

Abnormal Combustion Noise in Gas Appliances

During development of a new boiler, furnace, or other gas-fired appliance, tonal noise can be unacceptable. Because the frequency of the tone is equal to a resonance frequency of the system, this problem is often called a *combustion resonance*, but this term is misleading: changing the appliance's resonance frequency merely changes the frequency of the tone without much effect on the amplitude.

The proper term is **combustion-driven oscillation**, which is caused by feedback instability. Pressure oscillations in the combustion chamber (which manifest themselves as objectionable noise) also interact with the flame, modulating the instantaneous rate of combustion, which, in turn, causes more pressure oscillations (Putnam 1971). This feedback involves the acoustic response of the combustion chamber and of the fuel-air supply system, as well as that of the flame. For some combinations of response properties, the feedback loop is unstable. Instabilities may result from either perturbation of the mixture flow or of the air/fuel ratio. Instability because of a fluctuating air/fuel ratio is more likely to occur at low frequencies (Herrin et al. 2012).

The feedback loop suggested by Baade (1978) and modified by ASHRAE research project RP-1517 (Herrin et al. 2012) is very useful for understanding and solving oscillation problems. Baade identified three transfer functions that must be determined. Transfer functions Z and H are acoustic and can be determined experimentally or by simulation. Transfer function G_f is related to the flame and is best determined experimentally, though a few models are available. Figure 7 shows a schematic of Baade's feedback loop stability model for predicting combustion oscillations. Perturbations to the volume velocity of the flame, which are external to the feedback loop, are indicated by $\tilde{q}_{ext}$. The driving point impedance Z of the combustion chamber is the ratio of the oscillating pressure $\tilde{p}$ to the volume velocity in the combustion chamber $\tilde{q}_{tot}$ or $\tilde{Q}$. The transfer function H relates the perturbation of the mixture flow $\tilde{q}_i$ to the acoustic pressure in the combustion chamber $\tilde{p}$. As shown in Figure 7, the acoustic impedance of the chamber relates the flame perturbations to the sound pressure in the chamber. Acoustic impedance is primarily a function of the geometry of the combustion chamber and length of the exhaust. The sound pressure in the chamber in turn modulates either the mixture supply or air/fuel ratio. The respective transfer functions relating the sound pressures to the mixture supply or air/fuel ratio fluctuations are mainly controlled by the geometry of the intake. Mixture supply or air/fuel ratio fluctuations then drive the flame perturbations completing the feedback loop. The flame transfer function, which relates flame perturbations to the mixture supply and air/fuel ratio fluctuations, is related to several factors, including the burner type.

Predicting instability in a design is generally not practical for domestic or small commercial appliances because there is not enough information to predict the acoustic response of some of the components, particularly the flame.

A model of the feedback loop is very useful, however, for solving existing oscillation problems, where the only concern is the particular frequency at which the oscillation occurs. Reducing the response of the flame, air/fuel mixture supply, or combustion chamber at that frequency should be the focus. This concept can be easily

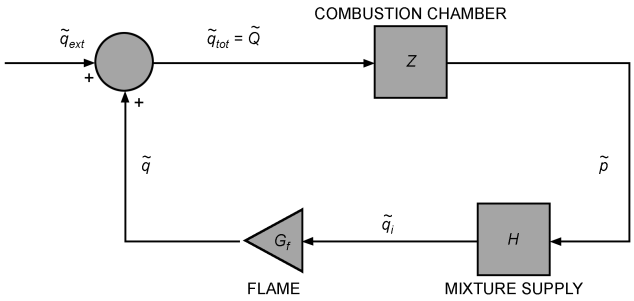

Fig. 7 Feedback Loop Stability Model Defined by Baade (1978, 2004)
(Herrin et al. 2012)

demonstrated with a small brazing torch in a tube of variable length (Baade 1987, 2004).

In some systems, the flame can be modified to reduce its response at the oscillation frequency. Often, this involves simply changing the fuel/air ratio further away from the stochiometric ratio (Elsari and Cummings 2003; Goldschmidt et al. 1978), thus lengthening the flame, which can also be done by increasing the size of burner ports (Matsui 1981; Schimmer 1979). Other possibilities for reducing flame response are using a suitable mix of differently sized burner ports (Kagiya 2000) and modifying the heat transfer characteristics of the burner matrix (Schreel et al. 2002).

The fuel supply system response can be reduced by avoiding resonance at or near the frequency of oscillation (Kilham et al. 1964) or by tuning the supply system to an antiresonance at that frequency (Neumann 1974). Higher-flow-resistance burners add acoustic damping to the fuel supply system. Designs for this can be evaluated by modeling the mixture supply system using transmission matrices (Munjal 1987) and computer programs for matrix multiplication, which are widely available (Baade and Tomarchio 2008).

Be careful to avoid any unnecessary resonances in the combustion chamber (Herrin et al. 2012). Structural resonances are sometimes the primary cause of a combustion oscillation, and can be identified by using an impact hammer and measuring the components' vibrational response using an accelerometer. Increasing damping can effectively resolve instabilities, if the system can increase damping enough: any damping less than the critical amount will have very little effect. Acoustic damping or sound absorption can be added by installing perforated panels or fiber. However, damping treatments are only likely to be effective for instabilities at high frequencies.

In some systems, the oscillation frequency may be a function of the flue pipe length. In such cases, consider changing the length as well as adding damping.

For large systems, active feedback may be used to eliminate combustion oscillations (Sattinger et al. 2000). However, active feedback is not likely to be cost effective for residential and small commercial systems.

Soot

Soot deposits on flue surfaces of a boiler or heater act as an insulating layer over the surface, reducing heat transfer to the water or air. Soot can also clog flues, reduce draft and available air, and prevent proper combustion. Proper burner adjustment can minimize soot accumulation. Using off-specification fuel can contribute to soot generation.

REFRIGERANTS are the working fluids in refrigeration, air-conditioning, and heat-pumping systems. They absorb heat from one area, such as an air-conditioned space, and reject it into another, such as outdoors, usually through evaporation and condensation, respectively. These phase changes occur both in absorption and mechanical vapor compression systems, but not in systems operating on a gas cycle using a fluid such as air. (See Chapter 2 for more information on refrigeration cycles.) The design of the refrigeration equipment depends strongly on the selected refrigerant's properties. Tables 1 and 2 list standard refrigerant designations, some properties, and safety classifications from ASHRAE *Standard* 34.

Refrigerant selection involves compromises between conflicting desirable thermophysical properties. A refrigerant must satisfy many requirements, some of which do not directly relate to its ability to transfer heat. Chemical stability under conditions of use is an essential characteristic. Safety codes may require a nonflammable refrigerant of low toxicity for some applications. Environmental consequences of refrigerant leaks must also be considered. Cost, availability, efficiency, compatibility with compressor lubricants and equipment materials, and local and national regulations are other concerns.

Latent heat of vaporization is another important property. On a molar basis, fluids with similar boiling points have almost the same latent heat. Because compressor displacement is defined on a volumetric basis, refrigerants with similar boiling points produce similar refrigeration effect with a given compressor. On a mass basis, latent heat varies widely among fluids. Efficiency of a theoretical vapor compression cycle is maximized by fluids with low vapor heat capacity. This property is associated with fluids having a simple molecular structure and low molecular mass.

Transport properties (e.g., thermal conductivity and viscosity) affect performance of heat exchangers and piping. High thermal conductivity and low viscosity are desirable.

No single fluid satisfies all the attributes desired of a refrigerant; consequently, various refrigerants are used. This chapter describes the basic characteristics of various refrigerants, and Chapter 30 lists thermophysical properties.

1. REFRIGERANT PROPERTIES

Global Environmental Properties

Chlorofluorocarbons (CFCs) and hydrochlorofluorocarbons (HCFCs) can affect both stratospheric ozone and climate change, whereas hydrofluorocarbons (HFCs) can affect climate change. Minimizing all refrigerant releases from systems is important not only because of environmental impacts, but also because charge losses lead to insufficient system charge levels, which in turn result in suboptimal operation and lowered efficiency.

Stratospheric Ozone Depletion. The stratospheric ozone layer filters out the UV-B portion of the sun's ultraviolet (UV) radiation. Overexposure to this radiation increases the risk of skin cancer, cataracts, and impaired immune systems. It also can damage sensitive crops, reduce crop yields, and stress marine phytoplankton (and thus human food supplies from the oceans). In addition, exposure to UV radiation degrades plastics and wood.

Stratospheric ozone depletion has been linked to the presence of chlorine and bromine in the stratosphere. Chemicals with long atmospheric lifetimes can migrate to the stratosphere, where the molecules break down from interaction with ultraviolet light or through chemical reaction. Chemicals such as CFCs and HCFCs release chlorine, which reacts with stratospheric ozone.

Ozone-depleting substances, including CFCs and HCFCs, are to be phased out of production under the Montreal Protocol (UNEP 2009). In the United States, production and importation of CFCs were banned completely in 1996. HCFCs are being phased down, with complete phaseout set for 2030. In 2010, to meet the Montreal Protocol phasedown schedule, U.S. regulations banned production and importation of HCFC-142b and HCFC-22 for use in new equipment. Reclaimed CFC and HCFC refrigerants that meet the requirements of AHRI *Standard* 700 can continue to be used for servicing existing systems. A complete list of U.S. regulations for CFC and HCFC refrigerants, including phaseout schedules, may be found at www.epa.gov/ozone-layer-protection. A summary of the phaseout schedules for CFCs and HCFCs for both developed and developing countries may be found at www.unep.org/ozonaction/topics/hcfc.asp.

Global Climate Change. The average global temperature is determined by the balance of energy from the sun heating the earth and its atmosphere and of energy radiated from the earth and the atmosphere to space. **Greenhouse gases (GHGs)**, such as CO_2 and water vapor, as well as small particles trap heat at and near the surface, maintaining the average temperature of the Earth's surface about 34 K warmer than would be the case if these gases and particles were not present (the **greenhouse effect**).

Global warming (also called **global climate change**) is a concern because of an increase in the greenhouse effect from increasing concentrations of GHGs attributed to human activities. The major GHG of concern is CO_2 released to the atmosphere when fossil fuels (coal, oil, and natural gas) are burned for energy. Methane (CH_4), nitrous oxide (N_2O), CFCs, HCFCs, HFCs, hydrofluoroethers (HFEs), hydrofluoro-olefins (HFOs), perfluorocarbons (PFCs), nitrogen trifluoride (NF_3), and sulfur hexafluoride (SF_6) are also GHGs.

In 1988, the United Nations Environment Programme (UNEP) and the World Meteorological Organization (WMO) established the Intergovernmental Panel on Climate Change (IPCC) to provide an objective source of information about the causes of climate change, its potential environmental and socioeconomic consequences, and the adaptation and mitigation options to respond to it. According to the IPCC (2014), atmospheric concentration of carbon dioxide has increased by more than 40% over the past 250 years, primarily from burning fossil fuels, with some contribution from forestry and land use. Concentration of methane has increased by over 150%, and of nitrous oxide by about 20%. IPCC (2014) deems atmospheric concentrations of fluorochemicals, including fluorocarbon gases

The preparation of this chapter is assigned to TC 3.1, Refrigerants and Secondary Coolants.

Source: ANSI/ASHRAE *Standard* 34-2010.

[a]Molecular mass and normal boiling point are not part of this standard.

[b]Azeotropic refrigerants exhibit some segregation of components at conditions of temperature and pressure other than those at which they were formulated. Extent of segregation depends on the particular azeotrope and hardware system configuration.

[c]Exact composition of this azeotrope is in question, and additional experimental studies are needed.

[d]R-507, R-508, and R-509 are allowed designations for R-507A, R-508A, and R-509A because of a change in designations after assignment of R-500 through R-509. Corresponding changes were not made for R-500 through R-506.

(CFCs, HCFCs, and HFCs) and sulfur hexafluoride, to be about 2% of the 2010 GHG (CO_2 equivalent) emissions.

Global Environmental Characteristics of Refrigerants. Atmospheric release of CFC and HCFC refrigerants (see Table 3) contributes to depletion of the ozone layer. The measure of a material's ability to deplete stratospheric ozone is its **ozone depletion potential (ODP)**, a value relative to R-11's value of 1.0. It is the nonzero ODP of these refrigerants that led to the phaseout of their production and use under the Montreal Protocol.

The **global warming potential (GWP)** of a GHG is an index describing its relative ability to trap radiant energy compared to CO_2 (R-744), which has a very long atmospheric lifetime. Measurements of climate impact of refrigerant emissions are hence often reported in CO_2 equivalents. GWP may be calculated for any particular **integration time horizon (ITH)**. Typically, a 100 year ITH is used for calculation of GWPs for regulatory purposes, and may be designated as GWP_{100}. Halocarbons (CFCs, HCFCs, and HFCs) and many nonhalocarbons (e.g., hydrocarbons, carbon dioxide) are GHGs. HFOs, or unsaturated HFCs, and blends using them are being developed and promoted as low-GWP alternatives to the existing halocarbon refrigerants. HFOs are also GHGs but their GWPs are drastically lower than those of HFCs.

The energy refrigeration appliances consume is often produced from fossil fuels, which results in emission of CO_2, a contributor to global warming. This indirect effect associated with energy consumption is frequently much larger than the direct effect of refrigerant emissions. The **total equivalent warming impact (TEWI)** of an HVAC&R system is the sum of direct refrigerant emissions expressed in terms of CO_2 equivalents, and indirect emissions of CO_2 from the system's energy use over its service life (Fischer et. al. 1991). Another measure is **life-cycle climate performance (LCCP)**, which includes TEWI and adds direct and indirect emissions effects associated with manufacturing the refrigerant and end-of-life disposal (ARAP 1999).

Ammonia (R-717), hydrocarbons, HCFCs, most HFCs, and HFOs have shorter atmospheric lifetimes than CFCs because they are largely destroyed in the lower atmosphere by reactions with OH radicals. A shorter atmospheric lifetime generally results in lower ODP and GWP_{100} values.

Table 3A gives values for atmospheric lifetime, ODP, and GWP_{100} of refrigerants being phased out under the Montreal Protocol and of their replacements, alone or as components of blends from the IPCC (2007). Table 3B shows the latest scientific assessment values for these refrigerants and for new refrigerants developed since IPCC (2007) was published. Because HFCs do not contain chlorine or bromine, their ODP values are negligible (Ravishankara et al. 1994) and thus are shown as 0 in Tables 3A and 3B. Nonhalocarbon refrigerants listed have zero ODP and very low GWP_{100}.

As shown in Tables 3A and 3B, there are differences between the values stipulated for reporting under the Montreal and Kyoto protocols and the latest scientific values. These differences are not large enough to significantly alter design decisions based on the numbers in the table. All these values have rather wide error bands and may change with each assessment of the science. Changes in GWP assessments are largely dominated by changes in understanding of CO_2, which is the reference chemical.

Table 4 provides ODP values for blends based on Montreal Protocol reporting values of the component fluids (Table 3A). It also gives IPCC (2007, 2013) GWP_{100} values based on component fluid values in Tables 3A and 3B, respectively.

Physical Properties

Table 5 lists some physical properties of commonly used refrigerants, a few very-low-boiling-point cryogenic fluids, some newer refrigerants, and some older refrigerants of historical interest, arranged in increasing order of atmospheric boiling point.

Table 5 also includes the freezing point, critical properties, and refractive index. Of these properties, normal boiling point is most important because it is a direct indicator of the temperature at which a refrigerant can be used. The freezing point must be lower than any contemplated usage. The critical properties describe a material at the point where the distinction between liquid and gas is lost. At higher temperatures, no separate liquid phase is possible for pure fluids. In refrigeration cycles involving condensation, a refrigerant must be chosen that allows this change of state to occur at a temperature somewhat below the critical. Cycles that reject heat at supercritical temperatures (e.g., cycles using carbon dioxide) are also possible.

Lithium Bromide/Water and Ammonia/Water Solutions. These are the most commonly used working fluids in absorption refrigeration systems. (See Chapter 30 for property data.)

Electrical Properties

Tables 6 and 7 list electrical characteristics of refrigerants that are especially important in hermetic systems.

Sound Velocity

The practical velocity of a gas in piping or through openings is limited by the velocity of sound in the gas. Chapter 30 has sound velocity data for many refrigerants. The velocity increases when temperature is increased and decreases when pressure is increased. REFPROP software (NIST 2010) can be used to calculate the sound velocity at superheated conditions. The velocity of sound can be calculated from the equation

$$V_a = \sqrt{(dp/d\rho)_S} = \sqrt{\gamma(dp/d\rho)_T} \quad (1)$$

where

V_a = sound velocity, m/s
p = pressure, Pa
ρ = density, kg/m^3
$\gamma = c_p/c_v$ = ratio of specific heats
S = entropy, kJ/(kg·K)
T = temperature, K

Sound velocity can be estimated from tables of thermodynamic properties. Change in pressure with a change in density ($dp/d\rho$) can be estimated at either constant entropy or constant temperature. It is simpler to estimate at constant temperature, but the ratio of specific heats must also be known.

2. REFRIGERANT PERFORMANCE

Chapter 2 describes several methods of calculating refrigerant performance, and Chapter 30 includes tables of thermodynamic properties of refrigerants.

Table 8 shows the theoretical calculated performance of a number of refrigerants for a standard cycle of various evaporation temperatures and 303 K condensation. For blend refrigerants, the average temperature in the evaporator and condenser is used. In most cases, suction vapor is assumed to be saturated, and compression is assumed adiabatic or at constant entropy. For R-113 and R-600a, for example, these assumptions cause some liquid in the discharge vapor. In these cases, it is assumed that discharge vapor is saturated and that suction vapor is slightly superheated. Note that actual operating conditions and performance may differ significantly from numbers in the table because of additional factors such as compressor efficiency and transport properties.

3. SAFETY

Tables 1 and 2 summarize toxicity and flammability characteristics of many refrigerants. In ASHRAE *Standard* 34, refrigerants are classified according to the hazard involved in their use. The toxicity and flammability classifications yield six safety groups (A1, A2, A3, B1, B2, and B3) for refrigerants. Group A1 refrigerants are the least hazardous, group B3 the most hazardous.

The letter designates toxicity class based on allowable exposure:

- Class A: Refrigerants that have an occupational exposure limit (OEL) of 400 ppm or greater.
- Class B: Refrigerants that have an OEL of less than 400 ppm.

[3]*Handbook of Chemistry* (1967).

The numeral denotes flammability:

- Class 1: No flame propagation in air at 60°C and 101.3 kPa
- Class 2: Exhibits flame propagation in air at 60°C and 101.3 kPa, lower flammability limit (LFL) greater than 0.10 kg/m³ at 23°C and 101.3 kPa, and heat of combustion less than 19 000 kJ/kg
- Optional class 2L: class 2 refrigerants may be classified as 2L if they exhibit a maximum burning velocity of no more than 100 mm/s at 23.0°C and 101.3 kPa
- Class 3: Exhibits flame propagation in air at 60°C and 101.3 kPa and LFL less than or equal to 0.10 kg/m³ at 23.0°C and 101.3 kPa or heat of combustion greater than or equal to 19 000 kJ/kg

Refrigerant blends are assigned the flammability safety classification of the worst case of fractionation of the blend (i.e., the composition during fractionation that results in the highest concentration of flammable components). For class 2 or 3 refrigerants or refrigerant blends that show no flame propagation when tested at

*Superheat required

Data from NIST CYCLE_D 4.0, zero subcool, zero superheat unless noted, no line losses, 100% efficiencies, average temperatures.

23.0°C and 101.3 kPa (i.e., no LFL), an elevated temperature flame limit at 60°C (ETFL60) is used in lieu of the LFL for determining flammability classifications.

4. LEAK DETECTION

Leak detection in refrigeration equipment is of major importance for manufacturers and service engineers.

Electronic Detection

Electronic detectors are widely used in manufacture and assembly of refrigeration equipment. Techniques include infrared, solid electrolyte semiconductor, heated electrode/diode, and corona discharge sensors. Instrument operation depends on the variation in signal caused by the presence of refrigerant. These instruments can be refrigerant specific or may detect a variety of refrigerants. Other vapors in the local environment may interfere with the test.

The electronic detector is the most sensitive of the methods discussed here, readily capable of sensing a leak of 2.8 g of refrigerant per year. A portable model is available for field testing. Other models are available with automatic balancing systems that correct for background refrigerant vapors that might be present in the atmosphere around the test area.

Bubble Method

The object to be tested is pressurized with air or nitrogen. A pressure corresponding to operating conditions is generally used. If possible, the object is fully immersed in water, and leaks are detected by observing bubbles in the liquid. Adding a detergent to the water decreases surface tension, prevents escaping gas from clinging to the side of the object, and promotes formation of a regular stream of small bubbles. In addition to dwell time, test sensitivity is influenced by clarity of the liquid, lighting, proximity of the leak site to

Licensed for single user. © 2021, ASHRAE, Inc.

the operator, and human factors. When immersion is not practical, a solution of soap can be brushed, sprayed, or poured onto joints or other spots where leakage is suspected. Leaking gas forms soap bubbles that can be readily detected. When properly performed under favorable conditions, bubble testing methods can detect leaks as small as 2.8 g of refrigerant per year.

Pressure Change Methods

The presence of leaks can be determined by pressurizing or evacuating the internals of the part or system and observing the change in pressure or vacuum over a period of time. The vacuum decay test can give an indication of proper dehydration but, like pressure decay, it does not locate the point of leakage. Test methods that are based on pressure change typically are not sensitive enough to meet the needs of refrigerant components and systems used in HVAC applications. The pressure change test methods are useful to verify that a component or system is free from gross leaks. Typical sensitivity is in the range of dozens of kilograms of refrigerant per year.

Leaks can also be determined by pressurizing or evacuating and observing the change in pressure or vacuum over a period of time. This is effective in checking system tightness but does not locate the point of leakage.

UV Dye Method

A stable UV-fluorescent dye is introduced into the system to be tested. Operating the system mixes the UV dye uniformly in the oil/refrigerant system. The dye, which usually prefers oil, shows up at the leak's location, and can be detected using an appropriate UV lamp. Ensure that the dye is compatible with system components and that no one is exposed to UV radiation from the lamp. This method only finds defects that are large enough to pass liquid, and will only work effectively in regions of the system where enough oil is available to carry the dye. Thus, this method's sensitivity is typically significantly lower than that of the electronic detection and bubble test methods.

Ammonia Leaks

Ammonia can be detected by any of the previously described methods, or by bringing a solution of hydrochloric acid near the object. If ammonia vapor is present, a white cloud or smoke of ammonium chloride forms. Ammonia can also be detected with indicator paper that changes color in the presence of a base. Ensure that adequate ventilation is provided and no one is exposed to ammonia.

5. COMPATIBILITY WITH CONSTRUCTION MATERIALS

Metals

Halogenated refrigerants can be used satisfactorily under normal conditions with most common metals, such as steel, cast iron, brass, copper, tin, lead, and aluminum [an important exception is methyl chloride (R-40) in contact with aluminum]. Under more severe conditions, various metals affect properties such as hydrolysis and thermal decomposition in varying degrees. The tendency of metals to promote thermal decomposition of halogenated compounds is in the following order:

(least decomposition) Inconel < 18-8 stainless steel < nickel < copper < 1040 steel < aluminum < bronze < brass < zinc < silver (most decomposition)

This order is only approximate, and there may be exceptions for individual compounds or for special use conditions (Downing 1988).

Magnesium alloys and aluminum containing more than 2% magnesium are not recommended for use with halogenated compounds where even trace amounts of water may be present. Zinc is not recommended for use with CFC-113. Experience with zinc and other fluorinated compounds has been limited, but no unusual reactivity has been observed under normal conditions of use in dry systems. However, OxyChem (2009) takes a more conservative position: "Aluminum, zinc, or magnesium equipment should never be allowed to come in contact with methyl chloride."

In 2011, several suspected substitutions of R-40-containing refrigerant mixtures for R-134a in aluminum-containing refrigeration and air-conditioning systems resulted in equipment failures, explosions, and even fatalities (Powell 2012; *WorldCargo News* 2011). Reactions of methyl chloride with aluminum are known (Dow 2007; Linde 2010; OxyChem 2009), and several publications advise not using aluminum containers for methyl chloride (Dow 2010; European Industrial Gases Association 2010). Studies are under way to quantify the reactivity of methyl chloride concentrations in R-134a/aluminum systems, and identify methods of safe handling, neutralization, and disposal of R-40-contaminated refrigerants. R-40 contamination appears to be part of a broader global issue of fake and counterfeit refrigerants. Press reports [e.g., *ACR News* (2011a, 2011b, 2012)] describe discovery of R-40 and other contaminants, including hydrocarbons and illegal ozone-depleting substances, found in service market refrigerant containers with fake labels, and in refrigeration and air-conditioning systems on several continents, including North America. Using best practices in the service industry is essential, particularly using refrigerant identification methods to ensure refrigerant systems contain and are refilled with genuine refrigerant. Refrigerant manufacturers are developing additional means to deter counterfeit products.

Ammonia should never be used with copper, brass, or other alloys containing copper. Metals compatibility data for ammonia, carbon dioxide, and hydrocarbons are provided by Pruett (1995). Further information on compatibility of refrigerants and lubricants with construction materials metals, elastomers, and plastics is in Chapter 6 of the 2018 *ASHRAE Handbook—Refrigeration* and in publications of the Air-Conditioning, Heating, and Refrigeration Technology Institute (AHRTI), the research branch of the Air-Conditioning, Heating, and Refrigeration Institute (AHRI). For example, Rohatgi et al. (2012) investigated thermal and chemical stability of five refrigerants [HFO-1234yf, HFO-1234ze, R-32/HFO-1234yf (equal mass percentages), R-410A, and R-134a] and three lubricants (two types of POEs and a PVE). The report can be downloaded from AHRI's web site.

Elastomers

Linear swelling of some elastomers in the liquid phase of HCFC and HFC refrigerants is shown in Table 9 (Hamed et al. 1994). Swelling data can be used to a limited extent in comparing the effect of refrigerants on elastomers. However, other factors, such as the amount of extraction, tensile strength, and degree of hardness of the exposed elastomer, must be considered. When other fluids (e.g., lubricants) are present in addition to the refrigerant, the combined effect on elastomers should be determined. Extensive test

Table 9 Swelling of Elastomers in Liquid Refrigerants at Room Temperature, % Linear Swell

Refrigerant Number	Polyisoprene (Sulfur Cure)	Polychloroprene	Butyl Rubber	Styrene Butadiene Rubber	Nitrile Rubber	Fluoroelastomer
22	10.2	6.1	3.9	9.8	51.4	33.2
123	48.0	15.3	16.3	40.8	83.7	31.6
124	5.8	2.8	3.2	4.1	45.9	29.0
142b	10.2	6.5	6.2	7.3	8.7	31.8
32	2.7	1.0	1.0	2.0	8.3	23.2
125	4.2	2.7	2.6	3.6	3.9	11.7
134a	1.2	1.2	0.6	1.0	5.1	25.6
143a	1.9	1.2	1.3	1.5	2.0	13.6
152a	4.2	3.0	1.7	2.8	8.8	39.1

data for compatibility of elastomers and gasketing materials with refrigerants and lubricants are reported by Hamed et al. (1994). More recent elastomer compatibility data for R-134a and R-1234yf were reported by Minor and Spatz (2008). Six elastomers were contacted with the refrigerants and a PAG lubricant at 100°C for two weeks. Linear swell percentages for the elastomers were very similar in the tests: in the range of –1.4 to +2.1% with R-134a and –1.6 to +1.6% with R-1234yf. Mass gain and hardness changes for the elastomers were also similar in the tests, except for silicone elastomer in R-1234yf having a larger decrease in hardness.

Permeation of fluids through elastomers is another consideration, such as with elastomeric hoses in mobile air-conditioning systems. Refrigerant can be lost by outward permeation of refrigerant through the hoses, and water can enter the system by inward diffusion. Data for water and refrigerant permeation through many types of elastomers are presented by Downing (1988). Multilayer hose construction is used to significantly reduce water ingression and refrigerant permeation loss. A typical hose construction might be an outer cover of chlorobutyl elastomer to reduce water ingression, a layer of polyamide to reduce refrigerant permeation, and the inner tube of chloroprene. Hose manufacturers offer variations of such constructions based on their proprietary technology. Refrigerant permeation test data for R-134a and R-1234yf through these types of hose constructions were reported by Minor and Spatz (2008) and Hill and Grimm (2008). In all cases, the permeation rates of R-1234yf were lower than those of R-134a. Majurin et al. (2014) also investigated materials compatibility of HFO-1234yf, HFO-1234ze, and a blend of 1234yf/1234ze/R-32 (equal mass percentages) with various elastomers and other motor materials, and found a wide range of compatible materials; the report is available on AHRI's website.

See Pruett (1994) for compatibility data for elastomers with ammonia, carbon dioxide, and hydrocarbons.

Plastics

The effect of a refrigerant on a plastic material should be thoroughly examined under conditions of intended use, including the presence of lubricants. Plastics are often mixtures of two or more basic types, and it is difficult to predict the refrigerant's effect. Mass and visual changes can be used as a general guide of effect, but changes in the plastic's properties should also be examined. Extensive test data for compatibility of plastics with refrigerants and lubricants are reported by Cavestri (1993), including 23 plastics, 10 refrigerants, 7 lubricants, and 17 refrigerant/lubricant combinations. Refrigerants and lubricants had little effect on most of the plastics, though acrylonitrile-butadiene-styrene, polyphenylene oxide, and polycarbonate were affected enough to be considered incompatible. In a separate study by DuPont Fluoroproducts (2003), acrylonitrile butadiene styrene and polystyrene were determined to have questionable compatibility with HCFC and HFC refrigerants.

R-134a and R-1234yf were evaluated for compatibility with typical plastics used in automotive air-conditioning systems (Minor and Spatz 2008). Five plastics (polyester, nylon, epoxy, polyethylene terephthalate, and polyimide) were contacted in sealed tubes containing the refrigerants and PAG lubricant, and held at 100°C for two weeks. The plastics were evaluated for changes in mass and appearance 24 h after test completion, finding essentially the same positive ratings of the two refrigerants with the plastics.

For data an compatibility of plastics with ammonia, carbon dioxide, and hydrocarbons, see Pruett (2000).

Additional Compatibility Reports

The Air-Conditioning, Heating, and Refrigeration Institute (AHRI) has supported research programs for refrigerants stability and materials compatibility through their Materials Compatibility and Lubricants Research (MCLR) Program, beginning in the early 1990s for replacements for CFCs. Resulting research reports are available from AHRI, with the following refrigerants stability/materials compatibility research topics: plastics (Cavestri 1993), lubricant additives (Cavestri 1997), system contaminants (Cavestri 2000), motor materials (Doerr and Kujak 1993; Doerr and Waite 1996), desiccants (Field 1995), elastomers (Hamed et al. 1994), and metals (Huttenlocher 1992). Cavestri et al. (2010) studied five refrigerants (R-417A, R-422D, R-424A, R-434A, and R-438A) and lubricants in contact with aluminum, copper, and steel coupons, and with nonmetallic materials of construction (elastomers, sealants, and plastics). They found, "A general, overall statement can be made that material changes for the R-22 alternative refrigerants investigated in this study do not have statistically significant differences compared to R-22 exposure in both time and temperature."

Two recent AHRI projects investigated materials compatibility of HFO refrigerants. Phase I covered thermal stability of 1234yf, 1234ze, and a 1234yf/R-32 blend with lubricants in the presence of metals (Rohatgi et al. 2012). Phase II focused on compatibility with plastics, elastomers, and motor materials (Majurin et al. 2014). Both reports show that HFOs have compatibility with a wide range of materials used in HVAC&R systems.

CHAPTER 30

THERMOPHYSICAL PROPERTIES OF REFRIGERANTS

THIS chapter presents data for thermodynamic and transport properties of refrigerants, arranged for the occasional user. The refrigerants have a thermodynamic property chart on pressure-enthalpy coordinates with an abbreviated set of tabular data for saturated liquid and vapor on the facing page. In addition, tabular data in the superheated vapor region are given for R-134a to assist students working on compression cycle examples.

For each cryogenic fluid, a second table of properties is provided for vapor at a pressure of one standard atmosphere; these data are needed when such gases are used in heat transfer or purge gas applications. For zeotropic blends, including R-729 (air), tables are incremented in pressure, with properties given for liquid on the bubble line and vapor on the dew line. This arrangement is used because pressure is more commonly measured in the field while servicing equipment; it also highlights the difference between bubble and dew-point temperatures (the "temperature glide" experienced with blends).

Most CFC refrigerants have been deleted. Tables for R-11, R-13, R-113, R-114, R-141b, R-142b, R-500, R-502, R-503, and R-720 (neon) may be found in the 1997 *ASHRAE Handbook—Fundamentals*. R-12 has been retained to assist in making comparisons. Hydrogen and parahydrogen (R-702 and R-702p) may be found in the 2009 *ASHRAE Handbook–Fundamentals*. A new table and diagram for R-1233zd(E) have been added, and the data for R-245fa and R-1234ze(E) have been revised. Viscosity data for R-1234yf have been revised. The formulations conform to international standards, where applicable: thermodynamic properties of R-12, R-22, R-32, R-123, R-125, R-134a, R-143a, R-152a, R-717 (ammonia), and R-744 (carbon dioxide) and refrigerant blends R-404A, R-407C, R-410A, and R-507 conform to ISO *Standard* 17584, Refrigerant Properties.

Reference states used for most refrigerants correspond to the international convention of 200 kJ/kg for enthalpy and 1 kJ/(kg·K) for entropy, both for saturated liquid at 0°C. Exceptions are water and fluids with very low critical temperatures (e.g., ethylene, cryogens).

These data are intended to help engineers make preliminary comparisons among unfamiliar fluids. For greater detail and a wider range of data, see the sources in the References.

Refrigerant	Page
Halocarbon Refrigerants

CHAPTER 31

PHYSICAL PROPERTIES OF SECONDARY COOLANTS (BRINES)

Salt-Based Brines 31.1
Inhibited Glycols 31.4
Halocarbons 31.12
Nonhalocarbon, Nonaqueous Fluids 31.12

IN many refrigeration applications, heat is transferred to a **secondary coolant**, which can be any liquid cooled by the refrigerant and used to transfer heat without changing state. These liquids are also known as **heat transfer fluids**, **brines**, or **secondary refrigerants**.

Other ASHRAE Handbook volumes describe various applications for secondary coolants. In the 2018 *ASHRAE Handbook—Refrigeration*, refrigeration systems are discussed in Chapter 13, their uses in food processing in Chapters 23 and 28 to 42, and ice rinks in Chapter 44. In the 2019 *ASHRAE Handbook—HVAC Applications*, solar energy use is discussed in Chapter 35, and snow melting and freeze protection in Chapter 51. Thermal storage is covered in Chapter 51 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*.

This chapter describes physical properties of the more common secondary coolants based on ethylene glycol, propylene glycol, sodium chloride, or calcium chloride and provides information on their use. Less widely used secondary coolants such as ethyl alcohol or potassium formate are not included in this chapter, but their physical properties are summarized in Melinder (2007). Physical property data for nitrate and nitrite salt solutions used for stratified thermal energy storage are presented by Andrepont (2012). The chapter also includes information on corrosion protection. Supplemental information on corrosion inhibition can be found in Chapter 49 of the 2019 *ASHRAE Handbook—HVAC Applications* and Chapter 13 of the 2018 *ASHRAE Handbook—Refrigeration*.

1. SALT-BASED BRINES

Physical Properties

Water solutions of calcium chloride and sodium chloride have historically been the most common refrigeration brines. Tables 1 and 2 list the properties of pure calcium chloride brine and sodium chloride brine. For commercial grades, use the formulas in the footnotes to these tables. For calcium chloride brines, Figure 1 shows specific heat, Figure 2 shows the ratio of mass of solution to that of water, Figure 3 shows viscosity, and Figure 4 shows thermal conductivity. Figures 5 to 8 show the same properties for sodium chloride brines.

Table 1 Properties of Pure Calcium Chloride* Brines

Pure $CaCl_2$, % by Mass	Specific Heat at 15°C, J/(kg·K)	Crystallization Starts, °C	Density at 16°C, kg/m³		Density at Various Temperatures, kg/m³			
			$CaCl_2$	Brine	−20°C	−10°C	0°C	10°C
0	4184	0.0	0.0	999				
5	3866	–2.4	52.2	1044			1042	1041

Brine applications in refrigeration are mainly in industrial machinery and in skating rinks. Corrosion is the principal problem for calcium chloride brines, especially in ice-making tanks where galvanized iron cans are immersed.

Ordinary salt (sodium chloride) is used where contact with calcium chloride is intolerable (e.g., the brine fog method of freezing fish and other foods). It is used as a spray to air-cool unit coolers to prevent frost formation on coils. In most refrigerating work, the lower freezing point of calcium chloride solution makes it more convenient to use.

Commercial calcium chloride, available as Type 1 (77% minimum) and Type 2 (94% minimum), is marketed in flake, solid, and solution forms; flake form is used most extensively. Commercial sodium chloride is available both in crude (rock salt) and refined grades. Because magnesium salts tend to form sludge, their presence in sodium or calcium chloride is undesirable.

Corrosion Inhibition

All brine systems must be treated to control corrosion and deposits. Historically, chloride-based brines were maintained at neutral pH and treated with sodium chromate. However, using chromate as a corrosion inhibitor is no longer deemed acceptable because of its detrimental environmental effects. Chromate has been placed on hazardous substance lists by several regulatory agencies. For example, the U.S. Agency for Toxic Substances and Disease Registry's (ATSDR 2016) *Priority List of Hazardous Substances* ranks hexavalent chromium 17th out of 275 chemicals of concern (based on frequency, toxicity, and potential for human exposure at National Priorities List facilities). Consequently, hexavalent chrome and several chromates are also listed on several state right-to-know hazardous substance lists, including New Jersey, California, Minnesota, Pennsylvania and others.

Instead of chromate, most brines use a sodium-nitrite-based inhibitor ranging from approximately 3000 mg/kg in calcium brines to 4000 mg/kg in sodium brines. Other, proprietary organic inhibitors are also available to mitigate the inherent corrosiveness of brines.

Before using any inhibitor package, review federal, state, and local regulations concerning the use and disposal of the spent fluids. If the regulations prove too restrictive, an alternative inhibition system should be considered.

2. INHIBITED GLYCOLS

Ethylene glycol and propylene glycol, when properly inhibited for corrosion control, are used as aqueous-freezing-point depressants (antifreeze) and heat transfer media. Their chief attributes are their ability to efficiently lower the freezing point of water, their low volatility, and their relatively low corrosivity when properly inhibited. Inhibited ethylene glycol solutions have better thermophysical properties than propylene glycol solutions, especially at lower temperatures. However, the less toxic propylene glycol is preferred for applications involving possible human contact or where mandated by regulations. If a heat transfer fluid may have incidental food contact, then it should be made from propylene glycol that meets U.S. Pharmacopeia (USP 2016) *Food Chemical Codex* (FCC) specifications. Avoid other, less pure grades of propylene glycol: they can contain toxic or unwanted impurities that also adversely affect performance characteristics (e.g., foaming propensity, corrosion).

Physical Properties

Ethylene glycol and propylene glycol are colorless, practically odorless liquids that are miscible with water and many organic compounds. Table 3 shows properties of the pure materials.

The freezing and boiling points of aqueous solutions of ethylene glycol and propylene glycol are given in Tables 4 and 5. Note that increasing the concentration of ethylene glycol above 60% by mass causes the freezing point of the solution to increase. Propylene glycol solutions above 60% by mass do not have freezing points. Instead of freezing, propylene glycol solutions supercool and become a glass (a liquid with extremely high viscosity and the appearance and properties of a noncrystalline amorphous solid). On the dilute side of the eutectic (the mixture at which freezing produces a solid phase of the same composition), ice forms on freezing; on the concentrated side, solid glycol separates from solution on freezing. The freezing rate of such solutions is often quite slow, but, in time, they set to a hard, solid mass.

Physical properties (i.e., density, specific heat, thermal conductivity, and viscosity) for aqueous solutions of ethylene glycol can be found in Tables 6 to 9 and Figures 9 to 12; similar data for aqueous solutions of propylene glycol are in Tables 10 to 13 and Figures 13 to 16. Densities are for aqueous solutions of industrially inhibited glycols, and are somewhat higher than those for pure glycol and water alone. Typical corrosion inhibitor packages do not significantly affect other physical properties. Physical properties for the two fluids are similar, except for viscosity. At the same concentration, aqueous solutions of propylene glycol are more viscous than solutions of ethylene glycol. This higher viscosity accounts for the majority of the performance difference between the two fluids.

The choice of glycol concentration depends on the type of protection required by the application. If the fluid is being used to prevent equipment damage during idle periods in cold weather, such as winterizing coils in an HVAC system, 30% by volume ethylene glycol or 35% by volume propylene glycol is sufficient. These concentrations allow the fluid to freeze. As the fluid freezes, it forms a slush that expands and flows into any available space. Therefore, expansion volume must be included with this type of protection. If the application requires that the fluid remain entirely liquid, use a concentration with a freezing point 3 K below the lowest expected temperature. Avoid excessive glycol concentration because it increases initial cost and adversely affects the fluid's physical properties.

Additional physical property data are available from suppliers of industrially inhibited ethylene and propylene glycol.

Corrosion Inhibition

Interestingly, ethylene glycol and propylene glycol, when not diluted with water, are actually less corrosive than water is with common construction metals. However, once diluted with water (as is typical), all aqueous glycol solutions are more corrosive than the water from which they are prepared: when uninhibited glycols thermally degrade and oxidize with use, they form acidic degradation products, which create an increasingly more corrosive environment if corrosion inhibitors and pH buffering compounds are not present. The amount of oxidation is influenced by temperature, degree of aeration, and type of metal components to which the glycol solution is exposed. In general, hydronic heating systems cause more degradation of glycol-based heat transfer fluids than do chilled-water systems. It is therefore necessary for glycol-based heat transfer fluids not only to use corrosion inhibitors that are effective at protecting common metals from corrosion, but also to contain additional additives to buffer or neutralize the acidic glycol degradation products that form during use. Corrosion inhibitors form a surface barrier that protects metal from attack, but their effectiveness is highly dependent on solution pH. Failure to compensate for glycol degradation

leads to a downward shift in solution pH, which negates the usefulness of some corrosion inhibitors (particularly for cast iron and carbon steels, but also solders). Properly inhibited glycol products should be used.

Service Considerations

Design Considerations. Inhibited glycols can be used at temperatures as high as 175°C. However, maximum-use temperatures vary from fluid to fluid, so the manufacturer's suggested temperature-use ranges should be followed. In systems with a high degree of aeration, the bulk fluid temperature should not exceed 65°C; however, temperatures up to 175°C are permissible in a pressurized system if air intake is eliminated. Maximum film temperatures should not exceed 28 K above the bulk temperature. Nitrogen blanketing minimizes oxidation when the system operates at elevated temperatures for extended periods.

Minimum operating temperatures for a recirculating fluid are typically –29°C for ethylene glycol solutions and –18°C for propylene glycol solutions. Operation below these temperatures is generally impractical, because the fluids' viscosity builds dramatically,

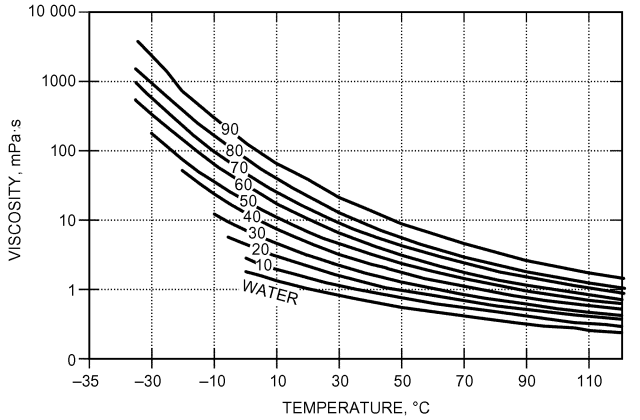

Fig. 16 Viscosity of Aqueous Solutions of Industrially Inhibited Propylene Glycol (vol. %)
(Dow Chemical 2001a)

Licensed for single user. © 2021 ASHRAE, Inc.

thus increasing pumping power requirements and reducing heat transfer film coefficients.

Standard materials can be used with most inhibited glycol solutions, except galvanized metals, which form insoluble zinc salts with the corrosion inhibitors. This depletes corrosion inhibitors below effective limits, and can cause excessive insoluble salt (sludge) formation.

Because removal of sludge and other contaminants is critical, install suitable filters. If inhibitors are rapidly and completely adsorbed by such contamination, the fluid is ineffective for corrosion inhibition. Consider such adsorption when selecting filters.

Storage and Handling. Inhibited glycol concentrates are stable, relatively noncorrosive materials with high flash points. These fluids can be stored in mild steel, stainless steel, or aluminum vessels. However, aluminum should be used only when the fluid temperature is below 65°C. Corrosion in the vapor space of vessels may be a problem, because the fluid's inhibitor package cannot reach these surfaces to protect them. A protective coating may be necessary (e.g., novolac-based vinyl ester resins, high-bake phenolic resins, polypropylene, polyvinylidene fluoride). To ensure the coating is suitable for a particular application and temperature, consult the manufacturer. Because the chemical properties of an inhibited glycol concentrate differ from those of its dilutions, the effect of the concentrate on different containers should be known when selecting storage.

Choose transfer pumps only after considering temperature/viscosity data. Centrifugal pumps with electric motor drives are often used. Materials compatible with ethylene or propylene glycol should be used for pump packing material. Mechanical seals are also satisfactory. Bypass or in-line filters are recommended to remove suspended particles, which can abrade seal surfaces. Welded mild steel transfer piping with a minimum diameter is normally used in conjunction with the piping, although flanged and gasketed joints are also satisfactory.

Preparation Before Application. Before an inhibited glycol is charged into a system, remove residual contaminants such as sludge, rust, brine deposits, and oil so the newly installed fluid functions properly. Avoid strong acid cleaners; if they are required, consider inhibited acids. Completely remove the cleaning agent before charging with inhibited glycol, because residual cleaning agents are known to cause system foaming problems.

Foaming. Adding glycols to water reduces surface tension and increases viscosity, particularly for propylene glycol, and this affects the rate at which dispersed gas bubbles coalesce and release to the surface of the liquid. If relatively high amounts of impurities accumulate either from the original source of glycol-based heat transfer fluid or from thermal oxidative degradation of the glycol, severe foaming problems may occur.

Dilution Water. Purified water such as distilled, deionized, or condensate water should be used whenever diluting or topping off a system. Nonpurified water contains corrosive ions and scale-promoting elements that reduce the effectiveness of the inhibited formulation. If purified water of this quality is unavailable, then ensure the source of water contains less than 25 mg/kg chloride, less than 25 mg/kg sulfate, and less than 100 mg/kg of total hardness before using.

Fluid Maintenance. Glycol concentrations can be determined by refractive index, gas chromatography, or Karl Fischer analysis for water (assuming that the concentration of other fluid components, such as inhibitor, is known). Using density to determine glycol concentration is unsatisfactory because (1) density measurements are temperature sensitive, (2) inhibitor concentrations can change density, (3) values for propylene glycol are close to those of water, and (4) propylene glycol values exhibit a maximum at 70 to 75% concentration.

An effective inhibitor monitoring and maintenance schedule is essential to keep a glycol solution relatively noncorrosive for a long period. Inspection immediately after installation, and annually thereafter, is normally an effective practice. Visual inspection of solution and filter residue can often detect potential system problems.

Many manufacturers of inhibited glycol-based heat transfer fluids provide analytical service to ensure that their product remains in good condition. This analysis may include some or all of the following: percent of ethylene and/or propylene glycol, freezing point, pH, reserve alkalinity, corrosion inhibitor evaluation, contaminants, total hardness, metal content, and degradation products. If maintenance on the fluid is required, recommendations may be given along with the analysis results.

Properly inhibited and maintained glycol solutions provide better corrosion protection than brine solutions in most systems. A long, though not indefinite, service life can be expected. Avoid indiscriminate mixing of inhibited formulations.

3. HALOCARBONS

Many common refrigerants are used as secondary coolants as well as primary refrigerants. Their favorable properties as heat transfer fluids include low freezing points, low viscosities, nonflammability, and good stability. Chapters 29 and 30 present physical and thermodynamic properties for common refrigerants.

Tables 1 and 2 in Chapter 29 summarizes comparative safety characteristics for halocarbons. ACGIH has more information on halocarbon toxicity threshold limit values and biological exposure indices (see the Bibliography).

Construction materials and stability factors in halocarbon use are discussed in Chapter 29 of this volume and Chapter 6 of the 2018 *ASHRAE Handbook—Refrigeration*.

4. NONHALOCARBON, NONAQUEOUS FLUIDS

Numerous additional secondary refrigerants, used primarily by the chemical processing and pharmaceutical industries, have been used rarely in the HVAC and allied industries because of their cost and relative novelty. Before choosing these types of fluids, consider electrical classifications, disposal, potential worker exposure, process containment, and other relevant issues.

Tables 14 to 16 list physical properties for a mixture of dimethylsiloxane polymers of various relative molecular masses (Dow Corning 1989) and d-limonene. Information on d-limonene is limited; it is based on measurements made over small temperature ranges or simply on standard physical property estimation techniques. The compound (molecular formula $C_{10}H_{16}$) is derived as an extract from orange and lemon oils.

The mixture of dimethylsiloxane polymers can be used with most standard construction materials; d-limonene, however, can be quite corrosive, easily autooxidizing at ambient temperatures. This fact should be understood and considered before using d-limonene in a system.

CHAPTER 32

SORBENTS AND DESICCANTS

Desiccant Applications 32.1
Desiccant Cycle 32.1
Types of Desiccants 32.3
Desiccant Isotherms 32.5
Desiccant Life 32.5
Cosorption of Water Vapor and Indoor Air Contaminants 32.5

SORPTION refers to the binding of one substance to another. **Sorbents** are materials that have an ability to attract and hold other gases or liquids. They can be used to attract gases or liquids other than water vapor, which makes them very useful in chemical separation processes. **Desiccants** are a subset of sorbents; they have a particular affinity for water.

Virtually all materials are desiccants; that is, they attract and hold water vapor. Wood, natural fibers, clays, and many synthetic materials attract and release moisture as commercial desiccants do, but they lack holding capacity. For example, woolen carpet fibers attract up to 23% of their dry mass in water vapor, and nylon can take up almost 6% of its mass in water. In contrast, a commercial desiccant takes up between 10 and 1100% of its dry mass in water vapor, depending on its type and on the moisture available in the environment. Furthermore, commercial desiccants continue to attract moisture even when the surrounding air is quite dry, a characteristic that other materials do not share.

All desiccants behave in a similar way: they attract moisture until they reach equilibrium with the surrounding air. Moisture is usually removed from the desiccant by heating it to temperatures between 50 and 205°C and exposing it to a scavenger airstream. After the desiccant dries, it must be cooled so that it can attract moisture once again. Sorption always generates sensible heat equal to the latent heat of the water vapor taken up by the desiccant plus an additional heat of sorption that varies between 5 and 25% of the latent heat of the water vapor. This heat is transferred to the desiccant and to the surrounding air.

The process of attracting and holding moisture is described as either adsorption or absorption, depending on whether the desiccant undergoes a chemical change as it takes on moisture. **Adsorption** does not change the desiccant, except by addition of the mass of water vapor; it is similar in some ways to a sponge soaking up water. **Absorption**, on the other hand, changes the desiccant. An example of an absorbent is lithium chloride, which changes from a solid to a liquid as it absorbs moisture.

1. DESICCANT APPLICATIONS

Desiccants can dry either liquids or gases, including ambient air, and are used in many air-conditioning applications, particularly when the

- Latent load is large in comparison to the sensible load
- Energy cost to regenerate the desiccant is low compared to the cost of energy to dehumidify the air by chilling it below its dew point and reheating it
- Moisture control level for the space would require chilling the air to subfreezing dew points if compression refrigeration alone were used to dehumidify the air
- Temperature control level for the space or process requires continuous delivery of air at subfreezing temperatures
- Air delivered to a space or ductwork must be at less than 70% rh

In any of these situations, the cost of running a vapor compression cooling system can be very high. A desiccant process may offer considerable advantages in energy, initial cost of equipment, and maintenance.

Because desiccants can attract and hold more than simply water vapor, they can remove contaminants from airstreams to improve indoor air quality. Desiccants have been used to remove organic vapors and, in special circumstances, to control microbiological contaminants (Battelle 1971; Buffalo Testing Laboratory 1974). Hines et al. (1991) also confirmed their usefulness in removing vapors that can degrade indoor air quality. Desiccant materials can adsorb hydrocarbon vapors while collecting moisture from air. These cosorption phenomena show promise of improving indoor air quality in typical building HVAC systems.

Desiccants are also used in drying compressed air to low dew points. In this application, moisture can be removed from the desiccant without heat. Desorption uses differences in vapor pressures compared to the total pressures of the compressed and ambient pressure airstreams.

Finally, desiccants are used to dry the refrigerant circulating in air-conditioning and refrigeration systems. This reduces corrosion in refrigerant piping and prevents valves and capillaries from becoming clogged with ice crystals. In this application, the desiccant is not regenerated; it is discarded when it has adsorbed its limit of water vapor.

This chapter discusses the water sorption characteristics of desiccant materials and explains some of the implications of those characteristics in ambient pressure air-conditioning applications. Information on other applications for desiccants can be found in Chapter 36 of this volume; Chapters 7, 8, 18, 39, and 44 of the 2018 *ASHRAE Handbook—Refrigeration*; Chapters 1, 2, 6, 10, 18, 20, 23, 30, and 46 of the 2019 *ASHRAE Handbook—HVAC Applications*; and Chapters 24 and 26 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*.

2. DESICCANT CYCLE

Practically speaking, all desiccants function the same way: by moisture transfer caused by a difference between water vapor pressures at their surface and of the surrounding air. When the vapor pressure at the desiccant surface is lower than that of the air, the desiccant attracts moisture. When the surface vapor pressure is higher than that of the surrounding air, the desiccant releases moisture.

Figure 1 shows the moisture content relationship between a desiccant and its surface vapor pressure. As the desiccant's moisture content rises, so does the water vapor pressure at its surface. At some point, the vapor pressure at the desiccant surface is the same as that of the air: the two are in equilibrium. Then, moisture cannot move in

The preparation of this chapter is assigned to TC 8.12, Desiccant Dehumidification Equipment and Components.

(Harriman 2003)

either direction until some external force changes the vapor pressure at the desiccant or in the air.

Figure 2 shows the effect of temperature on vapor pressure at the desiccant surface. Both higher temperature and increased moisture content increase surface vapor pressure. When surface vapor pressure exceeds that of the surrounding air, moisture leaves the desiccant (**reactivation** or **regeneration**). After the desiccant is dried (reactivated) by the heat, its vapor pressure remains high, so it has very little ability to absorb moisture. **Cooling** the desiccant reduces its surface vapor pressure so that it can absorb moisture again. The complete cycle is illustrated in Figure 3.

The economics of desiccant operation depend on the energy cost of moving a given material through this cycle. Dehumidifying air (loading the desiccant with water vapor) generally proceeds without energy input other than fan and pump costs. The major portion of energy is invested in regenerating the desiccant (moving from point 2 to point 3) and cooling the desiccant (point 3 to point 1).

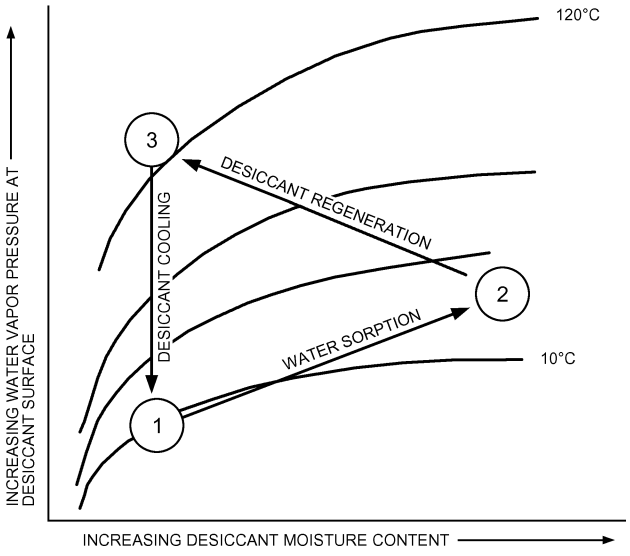

Fig. 3 Desiccant Cycle
(Harriman 2003)

Table 1 Vapor Pressures and Dew-Point Temperatures Corresponding to Different Relative Humidities at 21°C

Relative Humidity at 21°C, %	Dew Point, °C	Vapor Pressure, kPa
10	–10.5	0.25
20	–2.5	0.50
30	2.8	0.75
40	6.9	1.00
50	10.2	1.24
60	13.0	1.49
70	15.3	1.74
80	17.4	1.99
90	19.3	2.24
100	21.0	2.49

Regeneration energy is equal to the sum of the heat

- Necessary to raise the desiccant to a temperature high enough to make its surface vapor pressure higher than that of the surrounding air
- Necessary to vaporize the moisture it contains (about 2465 kJ/kg)
- From desorption of water from the desiccant (a small amount)

The **cooling energy** is proportional to the (1) mass of desiccant cycled and (2) difference between its temperature after regeneration and the lower temperature that allows the desiccant to remove water from the airstream again.

The cycle is similar when desiccants are regenerated using pressure differences in a compressed air application. The desiccant is saturated in a high-pressure chamber (i.e., that of the compressed air). Then valves open, isolating the compressed air from the material, and the desiccant is exposed to air at ambient pressure. The saturated desiccant's vapor pressure is much higher than ambient air at normal pressures; thus, moisture leaves the desiccant for the surrounding air. An alternative desorption strategy returns a small portion of dried air to the moist desiccant bed to reabsorb moisture, then vents that moist air to the atmosphere.

Table 1 shows the range of vapor pressures over which the desiccant must operate in space-conditioning applications. It converts the relative humidity at 21°C to dew point and the corresponding vapor

Licensed for single user. © 2021 ASHRAE, Inc.

pressure. The greater the difference between the air and desiccant surface vapor pressures, the greater the ability of the material to absorb moisture from the air at that moisture content.

The ideal desiccant for a particular application depends on the range of water vapor pressures likely to occur in the air, temperature of the regeneration heat source, and moisture sorption and desorption characteristics of the desiccant within those constraints. In commercial practice, however, most desiccants can be made to perform well in a wide variety of operating situations through careful engineering of mechanical aspects of the dehumidification system. Some of these hardware issues are discussed in Chapter 24 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*.

3. TYPES OF DESICCANTS

Desiccants can be liquids or solids and can hold moisture through absorption or adsorption, as described earlier. Most absorbents are liquids, and most adsorbents are solids.

Liquid Absorbents

Liquid absorption dehumidification can best be illustrated by comparison to air washer operation. When air passes through an air washer, its dew point approaches the temperature of water supplied to the machine. Air that is more humid is dehumidified, and air that is less humid is humidified. Similarly, a liquid absorption dehumidifier brings air into contact with a liquid desiccant solution. The liquid's vapor pressure is lower than water at the same temperature, and air passing over the solution approaches this reduced vapor pressure; it is dehumidified.

A liquid absorption solution's vapor pressure is directly proportional to its temperature and inversely proportional to its concentration. Figure 4 illustrates the effect of increasing desiccant concentration on the water vapor pressure at its surface. The figure shows the vapor pressures of various solutions of water and triethylene glycol, a commercial liquid desiccant. As the mixture's glycol content increases, its vapor pressure decreases. This lower pressure allows the glycol solution to absorb moisture from the air whenever the air's vapor pressure is greater than that of the solution.

Viewed another way, the vapor pressure of a given concentration of absorbent solution approximates the vapor pressure values of a fixed relative humidity line on a psychrometric chart. Higher solution concentrations give lower equilibrium relative humidities, which allow the absorbent to dry air to lower levels.

Figure 5 illustrates the effect of temperature on vapor pressures of various solutions of water and lithium chloride (LiCl), another common liquid desiccant. A solution that is 25% lithium chloride has a vapor pressure of 1.25 kPa at a temperature of 21°C. If the same 25% solution is heated to 37.8°C, its vapor pressure more than doubles to 3.3 kPa. Expressed another way, the 21°C, 25% solution is in equilibrium with air at a 10.5°C dew point. The same 25% solution at 37.8°C is at equilibrium with an airstream at a 26°C dew point. The warmer the desiccant, the less moisture it can attract from the air.

In standard practice, behavior of a liquid desiccant is controlled by adjusting its temperature, concentration, or both. Desiccant temperature is controlled by simple heaters and coolers. Concentration is controlled by heating the desiccant to drive moisture out into a waste airstream or directly to the ambient.

Commercially available liquid desiccants have an especially high water-holding capacity. Each molecule of LiCl, for example, can hold two water molecules, even in the dry state. Above two water molecules per molecule of LiCl, the desiccant becomes a liquid and continues to absorb water. If the solution is in equilibrium with air at 90% rh, approximately 26 water molecules are attached to each molecule of LiCl. This represents a water absorption of more than 1000% on a dry-mass basis.

As a practical matter, however, the absorption process is limited by the exposed surface area of desiccant and by the contact time allowed for reaction. More surface area and more contact time allow

the desiccant to approach its theoretical capacity. Commercial desiccant systems stretch these limits by flowing liquid desiccant onto an extended surface, much like in a cooling tower.

Solid Adsorbents

Adsorbents are solid materials with a tremendous internal surface area per unit of mass; a single gram can have more than 4600 m^2 of surface area. Structurally, adsorbents resemble a rigid sponge, and the surface of the sponge in turn resembles the ocean coastline of a fjord. This analogy indicates the scale of the different surfaces in an adsorbent. The fjords can be compared to the **capillaries** in the adsorbent. Spaces between the grains of sand on the fjord beaches can be compared to the spaces between the individual molecules of adsorbent, all of which have the capacity to hold water molecules. The bulk of adsorbed water is contained by condensation into the capillaries, and the majority of the surface area that attracts individual water molecules is in the crystalline structure of the material itself.

Adsorbents attract moisture because of the electrical field at the desiccant surface. The field is not uniform in either force or charge, so specific sites on the desiccant surface attract water molecules that have a net opposite charge. When the complete surface is covered, the adsorbent can hold still more moisture because vapor condenses into the first water layer and fills capillaries throughout the material. As with liquid absorbents, an adsorbent's ability to attract moisture depends on the difference in vapor pressure between its surface and the air.

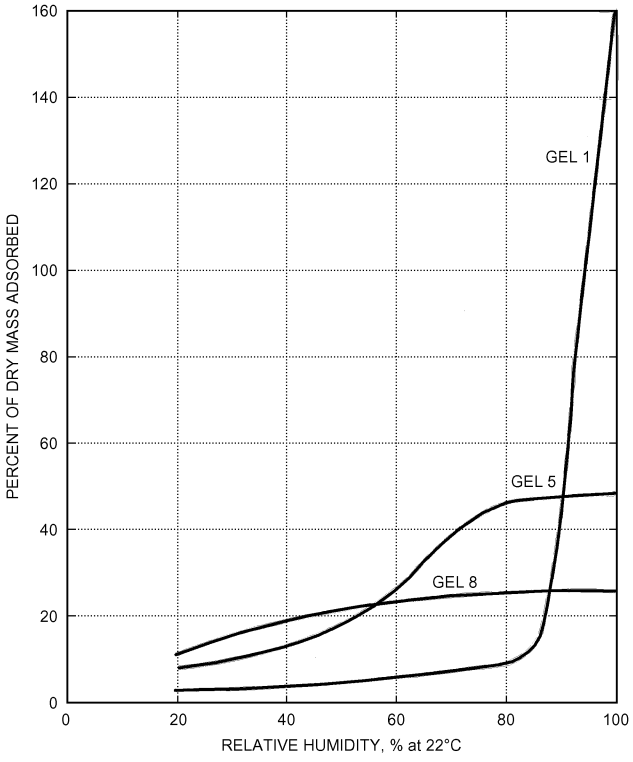
Capacity of solid adsorbents is generally less than the capacity of liquid absorbents. For example, a typical molecular sieve adsorbent can hold 17% of its dry mass in water when the air is at 21°C and 20% rh. In contrast, LiCl can hold 130% of its mass at the same temperature and relative humidity.

Solid adsorbents have several advantages, however. For example, molecular sieves continue to adsorb moisture even when they are quite hot, allowing dehumidification of very warm airstreams. Also, several solid adsorbents can be manufactured to precise tolerances, with pore diameters that can be closely controlled. This means they can be tailored to adsorb molecules of a specific diameter. Water, for example, has an effective molecular diameter of 0.32 nm. A molecular sieve adsorbent with an average pore diameter of 0.40 nm adsorbs water but has almost no capacity for larger molecules, such as organic solvents. This selective adsorption characteristic is useful in many applications. For example, several desiccants with different pore sizes can be combined in series to remove first water and then other specific contaminants from an airstream.

Adsorption Behavior. Adsorption behavior depends on (1) total surface area, (2) total volume of capillaries, and (3) range of capillary diameters. A large surface area gives the adsorbent a larger capacity at low relative humidities. Large capillaries provide a high capacity for condensed water, which gives the adsorbent a higher capacity at high relative humidities. A narrow range of capillary diameters makes an adsorbent more selective in the vapor molecules it can hold.

In designing a desiccant, some tradeoffs are necessary. For example, materials with large capillaries necessarily have a smaller surface area per unit of volume than those with smaller capillaries. As a result, adsorbents are sometimes combined to provide a high adsorption capacity across a wide range of operating conditions. Figure 6 illustrates this point using three noncommercial silica gel adsorbents prepared for use in laboratory research. Each has a different internal structure, but because they are all silicas, they have similar surface adsorption characteristics. Gel 1 has large capillaries, making its total volume large but its total surface area small. It has a large adsorption capacity at high relative humidities but adsorbs a small amount at low relative humidities.

In contrast, gel 8 has a capillary volume one-seventh the size of gel 1, but a total surface area almost twice as large. This gives it a higher capacity at low relative humidities but a lower capacity to hold the moisture that condenses at high relative humidities.



Silica gels and most other adsorbents can be manufactured to provide optimum performance in a specific application, balancing capacity against strength, mass, and other favorable characteristics (Bry-Air 1986).

Types of Solid Adsorbents. General classes of solid adsorbents include

- Silica gels
- Zeolites
- Synthetic zeolites (molecular sieves)
- Activated aluminas
- Carbons
- Synthetic polymers

Silica gels are amorphous solid structures formed by condensing soluble silicates from solutions of water or other solvents. Advantages include relatively low cost and relative simplicity of structural customizing. They are available as large as spherical beads about 5 mm in diameter or as small as grains of a fine powder.

Zeolites are aluminosilicate minerals. They occur in nature and are mined rather than synthesized. Zeolites have a very open crystalline lattice that allows molecules such as water vapor to be held inside the crystal itself, like an object in a cage. Particular atoms of

Gel Number	Total Surface Area, m^2/g	Average Capillary Diameter, nm	Total Volume of Capillaries, mm^3/g
1	315	21	1700
5	575	3.8	490
8	540	2.2	250

(from data of Oscic and Cooper 1982)

Licensed for single user. © 2021 ASHRAE, Inc.

an aluminosilicate determine the size of the openings between the "bars" of the cage, which in turn governs the maximum size of the molecule that can be adsorbed into the structure.

Synthetic zeolites, also called **molecular sieves**, are crystalline aluminosilicates manufactured in a thermal process. Controlling process temperature and composition of ingredient materials allows close control of the adsorbent's structure and surface characteristics. At a somewhat higher cost, this provides a much more uniform product than naturally occurring zeolites.

Activated aluminas are oxides and hydrides of aluminum that are manufactured in thermal processes. Their structural characteristics can be controlled by the gases used to produce them and by the temperature and duration of the thermal process.

Carbons are most frequently used for adsorption of gases other than water vapor because they have a greater affinity for the nonpolar molecules typical of organic solvents. Like other adsorbents, carbons have a large internal surface and especially large capillaries. This capillary volume gives them a high capacity to adsorb water vapor at relative humidities of 45 to 100%.

Synthetic polymers have potential for use as desiccants, as well. Long molecules, like those found in polystyrenesulfonic acid sodium salt (PSSASS), are twisted together like strands of string. Each of the many sodium ions in the long PSSASS molecules has the potential to bind several water molecules, and the spaces between the packed strings can also contain condensed water, giving the polymer a capacity exceeding that of many other solid adsorbents.

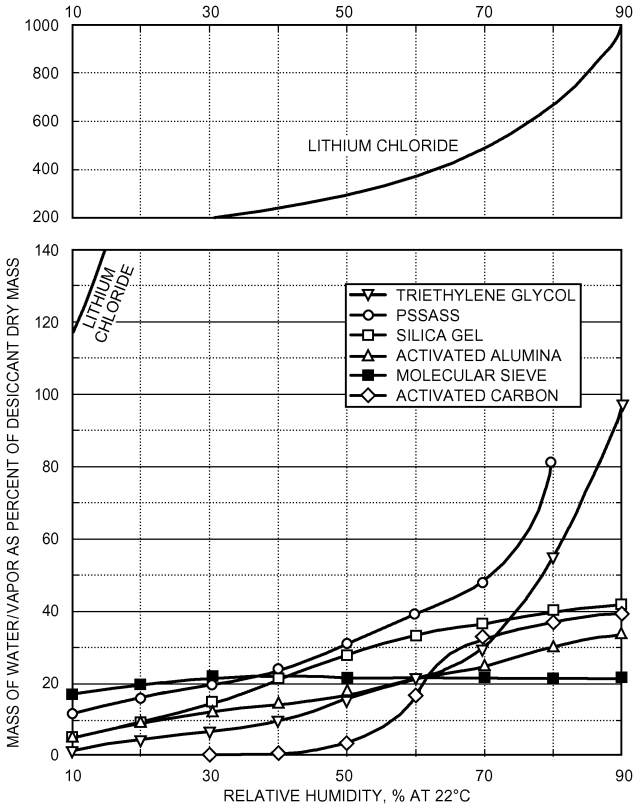
4. DESICCANT ISOTHERMS

Figure 7 shows a rough comparison of sorption characteristics of different desiccants. Large variations from these isotherms occur because manufacturers use different methods to optimize materials for different applications. Suitability of a given desiccant to a particular application generally depends as much on the engineering of the mechanical system that presents the material to airstreams as on the characteristics of the material itself.

Several sources give details of desiccant equipment design and information about desiccant isotherm characteristics. Brunauer (1945) considers five basic isotherm shapes. Sing (1985) added a sixth isotherm shape and defined four types of hysteresis loops that are often identified with specific pore structures. Each shape is determined by the dominant sorption mechanisms of the desiccant, which give rise to its specific capacity characteristics at different vapor pressures. Isotherm shape can be important in designing the optimum desiccant for applications where a narrow range of operating conditions can be expected. Collier (1986, 1988) illustrates how an optimum isotherm shape can be used to ensure a maximum coefficient of performance in one particular air-conditioning desiccant application.

5. DESICCANT LIFE

The useful life of desiccant materials depends largely on the quantity and type of contamination in the airstreams they dry. In commercial equipment, desiccants last from 10 000 to 100 000 h or longer before they need replacement. Normally, three mechanisms cause loss of desiccant capacity: (1) change in desiccant sorption characteristics through **chemical reactions** with contaminants, (2) loss of effective surface area through clogging or **hydrothermal degradation**, or (3) clogging or masking the pore system's surface by **contaminants**.



Liquid absorbents are more susceptible to chemical reaction with airstream contaminants other than water vapor than are solid adsorbents. For example, certain sulfur compounds can react with LiCl to form lithium sulfate, which is not a desiccant. If the concentration of sulfur compounds in the airstream were below 10 mg/kg and the desiccant were in use 24 h a day, capacity reduction would be approximately 10 to 20% after three years of operation. If the concentration were 30 mg/kg, this reduction would occur after one year. In contaminated environments, equipment manufacturers often arrange filters to remove these products of reaction, and provide devices to replenish desiccant so that capacity stays constant.

Solid adsorbents tend to be less chemically reactive and more sensitive to clogging, a function of the type and quantity of particulate material in the airstream. Also, certain types of silica gel can be sensitive to saturated airstreams or to liquid moisture carried over from cooling coils into the desiccant bed. In more challenging applications, thermally stabilized desiccants are used in place of less durable materials.

In air-conditioning applications, desiccant equipment is designed to minimize the need for desiccant replacement in much the same way that vapor compression cooling systems are designed to avoid the need for compressor replacement. Unlike filters, desiccants are seldom intended to be frequently replaced during normal service in an air-drying application.

6. COSORPTION OF WATER VAPOR AND INDOOR AIR CONTAMINANTS

Hines et al. (1991) confirmed that many desiccant materials can collect common indoor pollutants while they collect water vapor from ambient air. This characteristic promises to become useful in

future air-conditioning systems where indoor air quality is especially important.

The behavior of different desiccant and vapor mixtures is complex, but in general, pollutant sorption reactions can be classified into five categories:

- Humidity-neutral sorption
- Humidity-reduced sorption
- Humidity-enhanced sorption
- Humidity-pollutant displacement
- Desiccant-catalyzed pollutant conversion

Humidity-reduced sorption is illustrated by the behavior of water vapor and chloroform on activated carbon. Sorption is humidity-neutral until relative humidity exceeds 45%, when the uptake of chloroform is reduced. The adsorbed water blocks sites that would otherwise attract and hold chloroform. In contrast, water and carbonyl chloride mixtures on activated carbon demonstrate humidity-enhanced sorption (i.e., sorption of the pollutant increases at high relative humidities). Hines et al. (1991) attribute this phenomenon to the high water solubility of carbonyl chloride.

CHAPTER 33

PHYSICAL PROPERTIES OF MATERIALS

VALUES in the following tables are in consistent units to assist the engineer looking for approximate values. For data on refrigerants, see Chapter 29; for secondary coolants, see Chapter 31. Chapter 26 gives more information on the values for materials used in building construction and insulation. Many properties vary with temperature, material density, and composition. The references document the source of the values and provide more detail or values for materials not listed here. The preparation of this chapter is assigned to TC 1.3, Heat Transfer and Fluid Flow.

OVERVIEW OF GLOBAL ENERGY RESOURCES 34.4
World Energy Resources 34.4
Carbon Emissions 34.7
U.S. Energy Use 34.7
U.S. Agencies and Associations 34.9

ENERGY used in buildings and facilities is responsible for 30 to 40% of the world's energy use, significantly impacting world energy resources. ASHRAE's work to reduce energy consumption in the built environment is equally as important as research on new, more sustainable energy sources in helping ensure a reliable and secure supply of energy for future generations.

Many governmental agencies regulate energy conservation, often through the procedures to obtain building permits. Required efficiency values for building energy use strongly influence selection of HVAC&R systems and equipment and how they are applied.

More information on sustainable design is available in the *ASHRAE GreenGuide* (2013) and in Chapter 35.

1. CHARACTERISTICS OF ENERGY AND ENERGY RESOURCE FORMS

The HVAC&R industry deals with energy forms as they occur on or arrive at a building site. Generally, these forms are fossil fuels (natural gas, oil, and coal) and electricity. Solar and wind energy are also available at most sites, as is biomass. Geothermal energy is available at some locations.

Fossil Fuels and Electricity

Most on-site energy for buildings in developed countries involves electricity and fossil fuels as energy sources. Both fossil fuels and electricity can be described by their energy content (joules). This implies that energy forms are comparable and that an equivalence can be established. In reality, however, they are only comparable in energy terms when they are used to generate heat. Fossil fuels, for example, cannot directly drive motors or energize light bulbs. Conversely, electricity gives off heat as a by-product regardless of whether it is used for running a motor or lighting a light bulb, and regardless of whether that heat is needed. Thus, electricity and fossil fuels have different characteristics, uses, and capabilities aside from any differences in their derivation.

Other differences between energy forms include methods of extraction, transformation, transportation, and delivery, and characteristics of the resource itself. Natural gas arrives at the site in virtually the same form in which it was extracted from the earth. Oil is processed (distilled) before arriving at the site; having been extracted as crude oil, it arrives at a given site as, for example, No. 2 oil or diesel fuel. Electricity is created (converted) from a different energy form, often a fossil fuel, which itself may first be converted to a thermal form. The total electricity conversion, generation, and distribution process includes energy losses governed largely by the laws of thermodynamics.

Fossil fuels undergo a conversion process by combustion (oxidation) and heat transfer to thermal energy in the form of steam or hot water. The conversion equipment is a boiler or a furnace in lieu of a generator, and conversion usually occurs on a project site rather than off site. (District heating or cooling is an exception.) Inefficiencies of fossil fuel conversion occur on site, whereas inefficiencies of most electricity generation occur off site, before the electricity arrives at the building site. (Cogeneration is an exception.)

Sustainability is an important consideration for energy use. The United Nations' Brundtland Report (UN 1987) stated that the development of the built environment is sustainable if it "meets the needs of the present without compromising the ability of future generations to meet their own needs." More information is in Chapter 35.

Forms of On-Site Energy

Fossil fuels and electricity are commodities that are usually metered or measured for payment at the facility's location. Solar or wind energy is freely available but does incur cost for the means to use it. Geothermal energy, which is not universally available, may or may not be a sold commodity, depending on the particular locale and local regulations. Chapter 34 of the 2019 *ASHRAE Handbook—HVAC Applications* has more information on geothermal energy.

The term **energy source** refers to on-site energy in the form in which it arrives at or occurs on a site (e.g., electricity, gas, oil, coal). **Energy resource** refers to the raw energy that (1) is extracted from the earth (wellhead or mine-mouth), (2) is used to generate the energy source delivered to a building site (e.g., coal used to generate electricity), or (3) occurs naturally and is available at a site (solar, wind, or geothermal energy). Some on-site energy forms require further processing or conversion into more suitable forms for the particular systems and equipment in a building or facility. For instance, natural gas or oil is burned in a boiler to produce steam or hot water, which is then distributed to various use points (e.g., heating coils in air-handling systems, unit heaters, convectors, fin-tube elements, steam-powered cooling units, humidifiers, kitchen equipment) throughout the building. Although the methods and efficiencies of these processes fall within the scope of the HVAC&R designer, *how* an energy source arrives at a given facility site is not under direct control. On-site energy choices, when available, may be controlled by the designer based in part on the present and projected future availability of the resources.

Energy sources used for heating may be natural gas, oil, coal, or electricity. Cooling may be produced by electricity, thermal energy, or natural gas. If electricity is generated on site, the generator may be driven by an engine or fuel cell that consumes fossil fuels or hydrogen on site, by a turbine using steam or gas directly, or by on-site renewable sources.

Nonrenewable and Renewable Energy Resources

From the standpoint of energy conservation, energy resources can be classified as either (1) nonrenewable resources, which have definite, although sometimes unknown, limitations; or (2) renewable resources, which have the potential to regenerate in a reasonable

The preparation of this chapter is assigned to TC 2.8, Building Environmental Impacts and Sustainability.

period. Resources used most in industrialized countries are nonrenewable (ASHRAE 2003).

Note that *renewable* does not mean an infinite supply. For instance, hydropower is limited by rainfall and appropriate sites, usable geothermal energy is available only in limited areas, and crops are limited by the available farm area and competing non-energy land uses. Other forms of renewable energy also have supply limitations.

Nonrenewable resources of energy include

- Coal
- Crude oil
- Natural gas
- Uranium or plutonium (nuclear energy)

Renewable resources of energy include

- Hydropower
- Solar
- Wind
- Geothermal
- Biomass (wood, wood wastes, and municipal solid waste, landfill methane, etc.)
- Tidal power
- Ocean thermal
- Crops (for alcohol production or as boiler fuel)

Environmental Considerations

The most widely recognized environmental impact from energy use in buildings is **greenhouse gas emissions;** carbon dioxide emissions is usually the most important greenhouse gas resulting from energy use in buildings. In this area, use of renewable resources and nuclear power generally results in no net greenhouse gas emissions, whereas fossil fuel energy use generally results in substantial greenhouse gas emissions.

However, note that the important issue is the amount of greenhouse gas emissions released into the air, not the amount of a fuel used. It has been argued that some biomass energy sources are not really carbon-free sources, because they result in carbon dioxide releases that are not directly offset by carbon dioxide capture through growing vegetation to replace the biomass fuel. Even for fossil fuel energy use, research is ongoing for carbon capture and sequestration for emissions from fossil fuel electric power plants. If the carbon dioxide from a fossil fuel energy source is not released into the atmosphere, there are no greenhouse gas emissions resulting from the use of that fuel.

In addition to greenhouse gases, there are also local air pollution issues from combustion of fuels. These include emissions of carbon monoxide, nitrogen oxides, sulfur dioxide, heavy metals, and particulates. These occur in the combustion of fossil fuels and biomass, and do not occur from the use of renewable energy (other than biomass) or nuclear power. Emissions of local air pollutants vary greatly, depending on design of the combustion equipment and controls technology used. Note that biomass energy sources may require similar mitigation measures to reduce local air emissions as would be required for fossil fuel energy sources.

1.1 ON-SITE ENERGY/ENERGY RESOURCE RELATIONSHIPS

An HVAC&R designer must select one or more forms of energy. Most often, these are fossil fuels and electricity, although installations are sometimes designed using a single energy source (e.g., only a fossil fuel or only electricity).

Solar energy normally impinges on the site (and on the facilities to be put there), so it affects the facility's energy consumption. The designer must account for this effect and may have to decide whether to make active use of solar energy. Other naturally occurring and distributed renewable forms such as wind power and geothermal (if available) might also be considered.

The designer should be aware of the relationship between on-site energy sources and raw energy resources, including how these resources are used and what they are used for. The relationship between energy sources and energy resources involves two parts: (1) quantifying the energy resource units expended and (2) considering the societal effect of depletion of one energy resource (caused by on-site energy use) with respect to others.

Quantifiable Relationships

As on-site energy sources are consumed, a corresponding amount of resources are consumed to produce that on-site energy. For instance, for every volume of No. 2 oil consumed by a boiler at a building site, some greater volume of crude oil is extracted from the earth. On leaving the well, the crude oil is transported and processed into its final form, perhaps stored, and then transported to the site where it will be used.

Even though natural gas often requires no significant processing, it is transported, often over long distances, to reach its final destination, which causes some energy loss. Electricity may have as its raw energy resource a fossil fuel, uranium, or an elevated body of water (hydroelectric generating plant).

Data are available to help determine the amount of resource use per delivered on-site energy source unit. In the United States, data are available from entities within the U.S. Department of Energy and from the agencies and associations listed at the end of this chapter.

A **resource utilization factor (RUF)** is the ratio of resources consumed to energy delivered (for each form of energy) to a building site. Specific RUFs may be determined for various energy sources normally consumed on site, including nonrenewable sources such as coal, gas, oil, and electricity, and renewable sources such as solar, geothermal, waste, and wood energy. With electricity, which may derive from several resources depending on the particular fuel mix of the generating stations in the region served, the overall RUF is the weighted combination of individual factors applicable to electricity and a particular energy resource. Grumman (1984) gives specific formulas for calculating RUFs.

There are great differences in the efficiency of equipment used in buildings. Although electricity incurs losses in its production, it is often much more efficient than direct fuel use at the building site, particularly for lighting or heat pump applications. Minimizing both energy cost and the amount of energy resources needed to accomplish a task effectively should be a major design goal, which requires consideration of both RUFs and end-use efficiency of building equipment.

Although a designer is usually not required to determine the amount of energy resources attributable to a given building or building site for its design or operation, this information may be helpful when assessing the long-range availability of energy for a building or the building's effect on energy resources. Fuel-quantity-to-energy-resource ratios or factors are often used, which suggests that energy resources are of concern to the HVAC&R industry.

Intangible Relationships

Energy resources should not simply be converted into common energy units (e.g., gigajoule) because the commonality gives a misleading picture of the equivalence of these resources. Other differences and limitations of each of the resources defy easy quantification. For instance, electricity used on a site can be generated from coal, oil, natural gas, uranium, or hydropower. The end result is the same: electricity at x kV, y Hz. However, the societal impact of a kilowatt-hour electricity generated by hydropower may not equal that of a kilowatt-hour generated by coal, uranium, domestic oil, or imported oil.

Licensed for single user. © 2021 ASHRAE, Inc.

Intangible factors such as safety, environmental acceptability, availability, and national interest also are affected in different ways by the consumption of each resource. Heiman (1984) proposes a procedure for weighting the following intangible factors:

National/Global Considerations

- Balance of trade
- Environmental impacts
- International policy
- Employment
- Minority employment
- Availability
- Alternative uses
- National defense
- Domestic policy
- Effect on capital markets

Local Considerations

- Exterior environmental impact
  - Air
  - Solid waste
  - Water resources
- Local employment
- Local balance of trade
- Use of distribution infrastructure
- Local energy independence
- Land use
- Exterior safety

Site Considerations

- Reliability of supply
- Indoor air quality
- Aesthetics
- Interior safety
- Anticipated changes in energy resource prices

1.2 SUMMARY

In HVAC&R system design, the need to address immediate issues such as economics, performance, and space constraints often prevents designers from fully considering the energy resources affected. Today's energy resources are less certain because of issues such as availability, safety, national interest, environmental concerns, and the world political situation. As a result, the reliability, economics, and continuity of many common energy resources over the potential life of a building being designed are unclear. For this reason, the designer of building energy systems must consider the energy resources on which the long-term operation of the building will depend. If the continued viability of those resources is reason for concern, the design should provide for, account for, or address such an eventuality.

2. ENERGY RESOURCE PLANNING

The energy supplier (or suppliers) in a particular jurisdiction must plan for that jurisdiction's future energy needs. For competitive energy markets where these decisions do not have high societal costs, these plans are made by energy suppliers and are not revealed to governmental authorities or the public more than is absolutely necessary, because of the advantage competitors could gain by this knowledge. For electricity (and, to a lesser extent, natural gas), significant societal issues are involved in energy resource planning decisions that cannot be made by energy suppliers without approval by many different groups. Issues include

- **Reliability**, which is affected by the diversity of supply sources available. For gas, this includes the number of geographic supply sources and pipelines; for electricity, it includes the percentage of generation from various fuel sources. Consider the projected future supply and reliability of energy resources, including the possibility of supply disruption by natural or political events, and the likelihood of future supply shortages, which could reduce reliability.
- **Reserve margins**, or the ratio of total supply sources to expected peak supply source needs. Reserve levels that are too high result in waste of resources, higher environmental costs, and possibly poor financial health of the energy suppliers. Reserves that are too low result in volatile and very high peak energy prices and reduced reliability.
- **Land use.** Energy production and transmission often require governmental cooperation to condemn private property for energy production and transmission facilities. Construction and maintenance are also regulated to protect wetlands, prevent toxic waste releases, and other environmental issues.

Note that some energy regulation plans provide no guidance at all on energy supplies, through integrated resource planning (IRP) or other methods. Energy suppliers choose whether to expand their capacity, and what types of fuel those facilities use, based on their own assessment of the future profitability of that investment. In these markets, decisions are made with little societal input other than permitting and pollution control regulations, just as a decision might be made by a manufacturer in an industry such as steel or paper. This does not mean that decisions are made independent of larger societal issues, because laws and regulations (e.g., tradable emissions credits, renewable portfolio standards) factor into the economic considerations of competing suppliers. There is simply more direct planning by governmental authorities, and more opportunities for public input, in the integrated resource planning process typically done by regulated utility providers, as described in more detail in the following.

2.1 INTEGRATED RESOURCE PLANNING (IRP)

In regulated utility markets, integrated resource planning is commonly used for planning significant new energy facilities, especially for electricity. Steps include (1) forecasting the amount of new resources needed and (2) determining the type and provider of this resource. Traditionally, the local utility provider forecasts future needs of a given energy resource, then either builds the necessary facility with the approval of regulators or uses a standard offer bid to determine what nonutility provider (or the utility itself) would provide the new energy resource.

Supplying new energy resources through either a standard bid process by a supplier or traditional utility regulation usually results in selection of the lowest-cost supply option, without regard for environmental costs or other societal needs. IRP allows a greater variety of resource options and allows environmental and other indirect societal costs to be given greater consideration.

IRP addresses a wider population of stakeholders than most other planning processes. Many regulatory agencies involve the public in the formulation and review of integrated resource plans. Customers, environmentalists, and other public interest groups are often prominent in these proceedings.

In deregulated energy markets, supplying markets with new energy resources is typically left up to competitive market forces. This has sometimes resulted in excessive reliance on one form of energy, such as natural gas generation. Another result has been highly volatile prices, when supply is not provided because of insufficient price signals, followed by much higher prices and energy shortages until new supply sources can be obtained (which may not be for several years because of the time required for construction and environmental approval processes). Energy efficiency and demand response programs are increasingly treated as an energy resource on a par with energy production options, with incentives and compensation provided for participants in these programs.

Licensed for single user. © 2021 ASHRAE, Inc.

Demand-side management (DSM) is a common option for providing new energy resources, especially for electricity. These are actions taken to reduce the demand for energy, rather than increase the supply of energy. DSM is desirable because its environmental costs are almost always lower than those of building new energy facilities. However, the following factors have caused a decline in the number of DSM programs:

- Building and equipment codes and standards are a highly efficient form of DSM, reducing energy use with much lower administrative costs than programs that reward installation of more efficient equipment at a single site. However, they are more subtle than traditional DSM programs and may not always be recognized as a form of DSM.
- Opening markets to competing suppliers makes it more difficult to administer and implement DSM programs. However, they are still possible if regulators wish to continue them, and set appropriate rules and regulations for the market to allow implementation of DSM programs.

Many IRP participants may be interested in only one aspect of the process. For example, the energy industry's main interest may be cost minimization, whereas environmentalists may want to minimize pollutant emissions and prevent environmental damage from construction of energy facilities. Participation by all affected interest groups helps provide the best overall solution for society, including indirect costs and benefits from these energy resource decisions.

2.2 TRADABLE EMISSION CREDITS

Increasingly, quotas and limits apply to emissions of various pollutants. Often, a market-based system of tradable credits is used with these quotas. A company is given the right to produce a given level of emissions, and it earns a credit, which can be sold to others, if it produces fewer emissions than that level. If one company can reduce its emissions at a lower cost than another, it can do so and sell the emissions credit to the second company and earn a profit from its pollution control efforts. In the United States, emissions quota and trading programs currently include sulfur dioxide (SO_2) and nitrogen oxides (NO_x), with plans to implement carbon dioxide (CO_2) trading now under consideration, as well. In Europe, emissions trading for CO_2 has been active for several years.

Designers must be aware of any regulations concerning pollutant emissions; failure to comply with these regulations may result in civil or criminal penalties for designers or their clients. However, understand the options available under these regulations. The purchase or sale of emissions credits may allow reduced construction or building operations costs if the equipment can overcomply at a lower cost than the cost of another source of emissions to comply, or vice versa. In some cases, documentation of energy savings beyond what codes and regulations require can result in receiving emissions credits that may be sold later.

3. OVERVIEW OF GLOBAL ENERGY RESOURCES

3.1 WORLD ENERGY RESOURCES

Data in this section are from the *Statistical Review of World Energy 2015* (BP 2015).

Production

Energy production trends, by leading producers and world regions, from 2004 to 2014 are shown in Figure 1.

World primary energy production increased 21.2% from 2004 to 2014, because strong economic growth occurred in countries such as China, which increased its energy production more than 60% since 2004. The largest total energy producers in 2014 were China (19%), the United States (16%), Russia (10%), and Saudi Arabia (7%). Together, they produced about 52% of the world's energy production. (*Note*: for this and for similar graphs, the "Europe and Eurasia" region consists of the nations of western Europe plus the countries comprised by the former Soviet Union.)

Total world energy production by resource type for 2004 and 2014 is shown in Figure 2. The greatest growth in energy production among major sources has been hydroelectricity, up nearly 33% in usage from 2004 to 2014, and coal, which has increased 30.3%, and natural gas, up 10.3%. Petroleum use only rose 7.1%. Nonhydroelectric renewables use more than doubled, but is still a small percentage of total world energy production (BP 2015).

Crude Oil. World crude oil production was 88.7 million barrels (10 577 000 m^3) per day in 2014. The biggest crude-oil-producing region in 2014 was the Middle East, with 32% of the total. Among individual countries, the United States (13.1%), Saudi Arabia (13.0%), and Russia (12.2%) were the leading countries, following by China and Canada, each with 4.8% of total production. Since

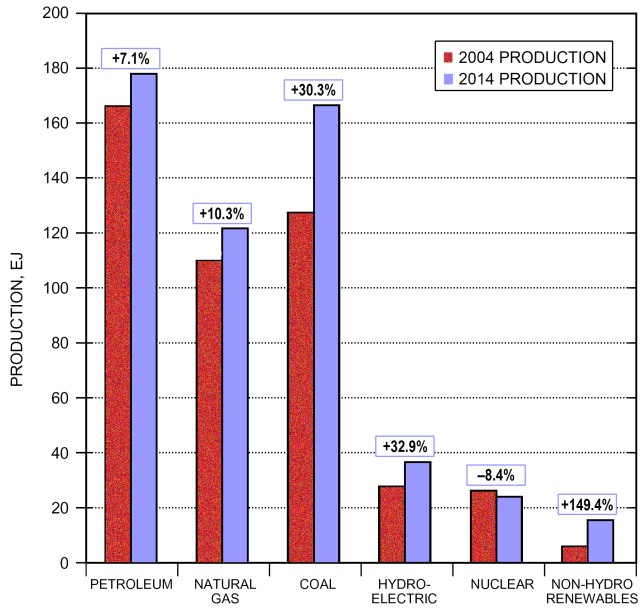

Fig. 2 World Primary Energy Production by Resource: 2004 Versus 2014
(Basis: EIA 2015)

Licensed for single user. © 2021 ASHRAE, Inc.

2004, oil production increased 56% in the United States and about 25% in both China and Russia.

Natural Gas. World production reached 3460.6 billion m^3 in 2014, up 14.4% from the 2004 level. The biggest producers in 2014 were the United States (22%), Russia (17%), Qatar (5%), Iran (5%), and Canada (5%). Since 2004, natural gas production in Qatar more than quadrupled, and was up 79% in Iran and 39% in the United States.

Coal. At 164.7 EJ in 2014, coal production was up 38.7% since 2004. Leading producers of coal were China (47%), the United States (13%), India (7%), and Indonesia (6%). Since 2004, Indonesia more than tripled coal production, China increased coal production 67%, and India increased 56%, whereas U.S. production fell by 11%.

Reserves

On January 1, 2015, estimated world reserves of crude oil and gas were distributed by world region as shown in Figures 3 and 4. Countries with the largest reported crude oil reserves are Venezuela (17.5%), Saudi Arabia (15.7%), Canada (10.2%), Iran (9.3%), and Iraq (8.8%). For natural gas, the countries with the largest reported reserves are Iran (18.2%), Russia (17.4%), Qatar (13.1%), Turkmenistan (9.3%), and the United States (5.2%).

Note that several factors make crude oil and natural gas reserve estimates less precise than some other energy statistics:

- For nations with national oil companies, reserve estimates are not verifiable by third parties, as is typically the case with the reserve estimates of publicly traded corporations.
- Technologies used for extracting hydrocarbons from nontraditional reserves (e.g., tar sands, shale deposits) are rapidly changing. This can result in very large revisions to reserve estimates that often lag production changes. For example, approximately 10 years ago, Canadian oil reserves rose substantially due to inclusion of tar sands in the total. More recently, reported crude oil and natural gas reserves in the United States have lagged production growth, because of uncertainty concerning the size of the total available resource that can be economically extracted.
- The definition of proved resource includes a requirement that it can be economically extracted, which can result in substantial changes due to fluctuations in the price of oil and natural gas.

World coal reserves as of January 1, 2015, are shown by region in Figure 5. The most plentiful reserves, as a percent of total, were in the United States (27%), Russia (18%), China (13%), Australia (9%), and India (7%).

An important factor is the relative amount of these energy resources that has not yet been consumed. A standard measure is called **proved energy reserves**, which is the remaining known deposits that could be recovered economically given current economic and operating conditions. Dividing proved reserves by the current production rate gives the number of years of the resource remaining. Using this measure, the reserve-to-production ratio at the end of 2014 for crude oil was 56.9 years; for natural gas, 55.0 years; and for coal, 109.2 years.

This does not mean that these resources will be depleted in that length of time: additional resources may be discovered in new areas, and improved technology may increase the amount of a resource that may be economically extracted. Also, the future rate of production and consumption may be higher or lower than current levels, which would decrease or increase the remaining years of a resource. However, reserve-to-production ratios provide insights into the limited nature of nonrenewable energy resources and the need to find alternatives, especially for resources with fewer years of remaining reserves.

Consumption

Data on world energy consumption are available only by type of resource rather than by total energy consumed.

Petroleum. Consumption trends of the leading consumers from 1965 to 2014 are depicted in Figure 6. In 2014, the United States consumed far more petroleum than any other country: 19.9% of the world total. Other major petroleum-consuming countries were China (12.4%), Japan (4.7%), Russia (3.5%), Brazil (3.4%), and Saudi Arabia (3.4%).

Natural Gas. In 2014, the two biggest natural gas producers (the United States and Russia) were also the two biggest consumers. Figure 7 depicts natural gas consumption by the leading consumer countries as a percentage of world consumption. The United States in 2014 consumed only 4% more than it produced, and Russia consumed 29% less than it produced. Of the other major natural-gas-consuming nations, China, Mexico, Germany, and the United Kingdom consumed at least 25% more than they produced. Iran, Saudi Arabia, and the United Arab Emirates were net consumers, but consumed less than 25% more than their production. Canada and Russia were the only major consuming nations that produced more than they consumed, but given current trends the United States is expected to be a net exporter of natural gas within a few years.

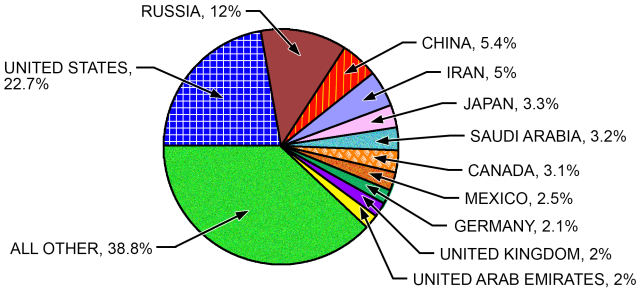

Fig. 7 World Natural Gas Consumption: 2014
(Basis: BP 2015)

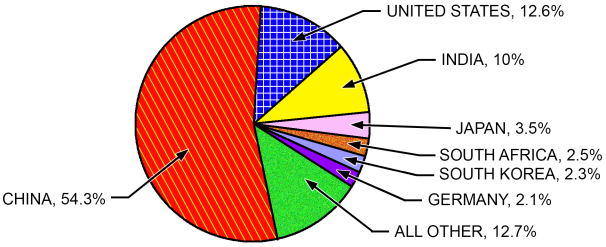

Fig. 8 World Coal Consumption: 2014
(Basis: BP 2015)

Coal. The two largest coal producers in 2014 (China and the United States) were also the two largest consumers. China is by far the largest coal consumer, with consumption more than four times that of the United States in 2014. Figure 8 depicts the percentage of world consumption by the leading consumers during 2014. Since 1980, world coal consumption has doubled, largely because of remarkable growth in coal consumption in China. Figure 9 shows the change in coal consumption since 1980 for the United States, China, and India. Over this span, consumption by China increased 544%, in India 535%, and in the United States 17%. However, coal consumption has been declining in the United States over the past 10 years, and growth in coal consumption in China has slowed dramatically since 2010. Growth of coal consumption in India has continued. Although not shown on the graph, coal consumption is declining in most European countries.

Electricity. Figure 10 shows the world's electricity generation by energy resource in 2002 and 2012. (*Note*: unlike other energy statistics, which generally include 2014 data, the most recent year in

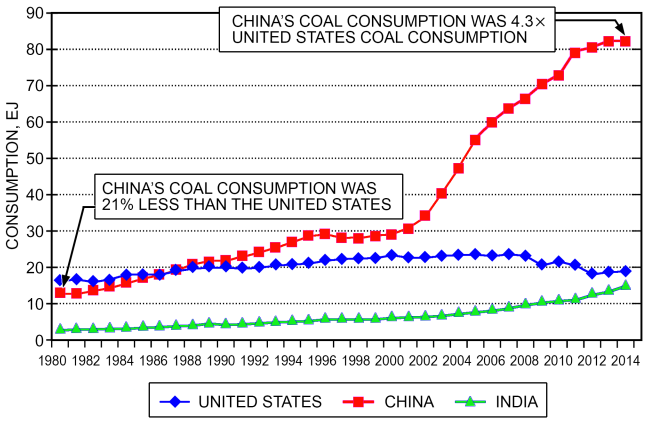

Fig. 9 Coal Consumption in United States, China, and India, 1980-2014
(Basis: BP 2015)

(EIA 2012)

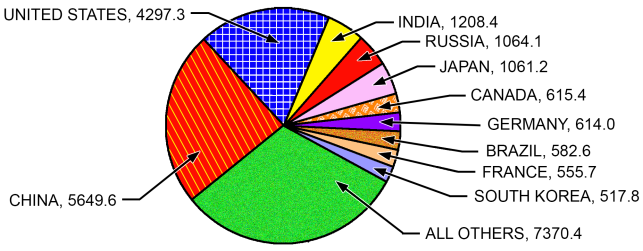

Fig. 11 World Electricity Generation 2014
(Basis: BP 2015)

which generation by fuel type is available is 2012.) Fossil fuel generation increased 45.3%, hydroelectric generation increased 39.9%, and nuclear generation decreased 7.9%, although this level of decrease may be temporary, driven by the shutdown of almost all nuclear generation in Japan during 2012. Nonhydroelectric renewable generation increased by the largest percentage (262.3%), but is still substantially less than the other resources.

Figure 11 shows total electricity generation by geographic region for 2014. China and the United States produced the most electricity, followed by India, Russia, and Japan.

Per Capita. Figure 12 compares the per capita energy consumption of selected countries for 2014. As is apparent, per capita energy

Licensed for single user. © 2021 ASHRAE, Inc.

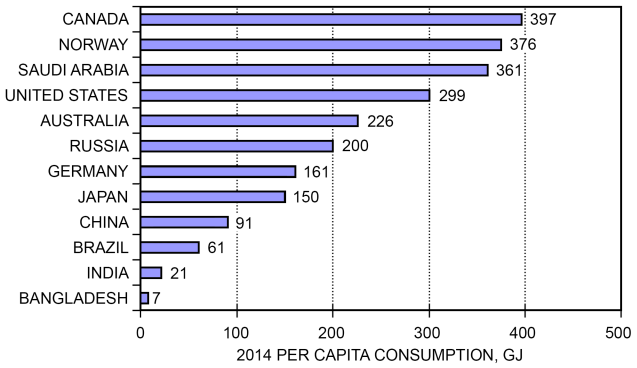

Fig. 12 Per Capita Energy Consumption by Selected Countries: 2011
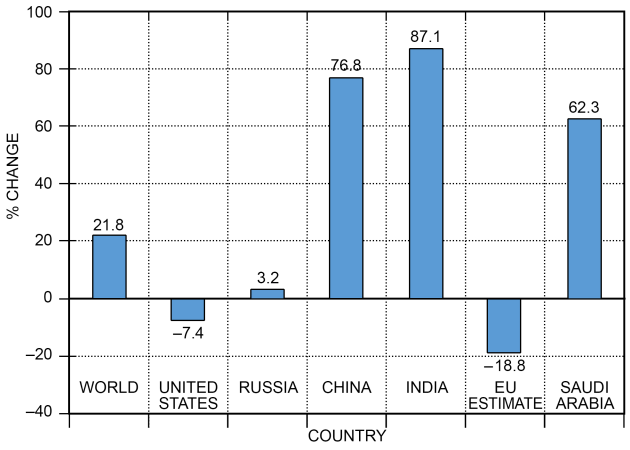
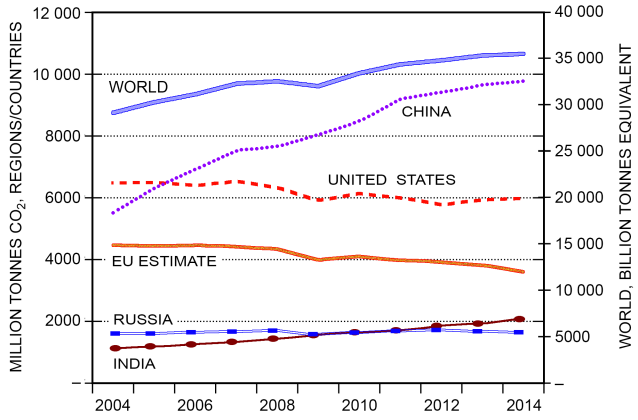
(Basis: BP 2015; CIA 2016)

consumption in countries with extreme weather, whether cold or hot, tends to be highest; also, the level in more developed countries is vastly different from that in less developed countries and differs considerably even among the more developed countries. Note that, although China's total energy use has grown very rapidly in recent years, on a per capita basis it is still substantially below the levels of more developed countries.



3.2 CARBON EMISSIONS

Worldwide carbon emissions from burning and flaring fossil fuels rose 21.8% from 2004 to 2014. Other sources of greenhouse gas emissions are included under international treaties; however, this section only shows the portion from marketed fossil fuel production, and so does not include greenhouse gas emissions from energy production, methane emission from various sources, or releases of high-global-warming-potential (GWP) chemicals such as refrigerants. Total carbon emissions were 35.499 billion tonnes of carbon dioxide in 2014, up from 29.143 billion tonnes in 2004. Figure 13A shows the changes in carbon emissions from burning fossil fuels from 2004 to 2014 for the total world and for selected countries. Greenhouse gas emissions dropped 7.4% in the United States, and dropped 18.8% in the European Union. Countries such as China, India, and Saudi Arabia showed the largest increases. Note that, although developing countries have the highest growth rates, their per capita carbon emissions are much less than in wealthier nations. A graph of per capita carbon emissions would look very similar to Figure 12, which shows per capita energy consumption of selected countries. Carbon emissions from fossil fuel use alone were not readily available for the EU as a whole. The data shown are for 22 of the 28 countries in the EU for which fossil fuel data was available by country. The six countries not included are very small, so the difference between the emissions shown and the EU total is not substantial.



3.3 U.S. ENERGY USE

Per Capita Energy Consumption

Figure 14, based on data from BP (2012), shows the growth in per capita energy use since 1965 for the world and for the United States. As can be seen in the graph, United States per capita energy use was approximately six times the world average in 1965, dropping to five times in 1985, and is now about four times the world average. Although the world average per capita energy use has steadily risen, U.S. per capita energy use peaked in the late 1960s, rose at a slow rate in the 1990s, and has generally declined in recent years.

Projected Overall Energy Consumption

The International Energy Outlook is a projection of total world energy use developed by the United States Department of Energy Information Administration (EIA 2016). Figure 15 shows projected energy consumption through the year 2040.

Licensed for single user. © 2021 ASHRAE, Inc.

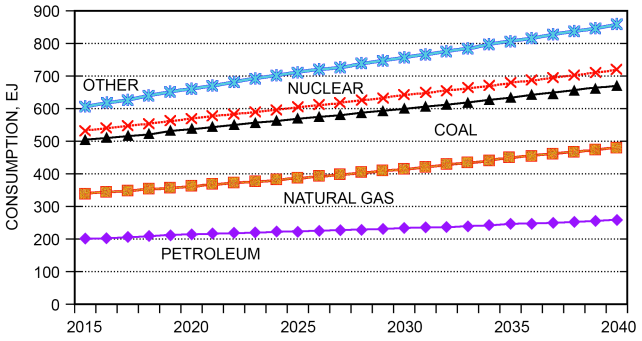

Fig. 15 Projected World Energy Consumption by Resource

Petroleum consumption is projected to increase by 1.10% percent per year, resulting in increased usage of 30% by 2040. Natural gas usage is projected to increase 1.90% per year, for a 64% increase by 2040. Coal is projected to increase 0.60% per year, for a 12% total increase. Nuclear power is projected to grow 2.3% yearly, for an 87% increase. "Other" energy sources, which includes renewables, are projected to grow at the highest rate, 2.60% annually, for an 87% increase by 2040.

The *Annual Energy Outlook* is the basic source of data for projecting energy use in the United States (EIA 2015). Figures 16 and 17 summarize data from this source. Information is available in greater detail for United States projected energy use than for world energy use.

EIA (2016) forecasts energy trends based on macroeconomic growth scenarios, which include a variety of energy price and economic growth assumptions. Figures 16 and 17 (the baseline or reference case) assume average annual growth of the real gross domestic product (GDP) at 2.2%, of the labor force at 0.7%, and of productivity at 1.7%. To be policy neutral, the forecast also assumes that all federal, state, and local laws and regulations in effect at the end of 2015 remain unchanged through 2040. *Note*: based on laws in effect at the end of 2015, this forecast assumes the implementation of the United States' Clean Power Plan, which proposed to reduce the allowable greenhouse gas emissions for existing electric power plants by 30% compared to 2005 levels (EPA 2016). However, later in 2016 this proposal was suspended, pending review by the United States Supreme Court. An alternative scenario developed by EIA assumed that the Clean Power Plan was not implemented, and projected less renewable energy growth and a lower rate of decline in coal consumption. Figure 16 shows energy use by major end-use sector (i.e., residential, commercial, industrial, and transportation). HVAC&R engineers are primarily concerned with the first three sectors. Figure 17 shows energy consumption by type of resource.

The following observations apply to the overall picture of projected energy use in the United States over the next two decades (Figures 16 and 17):

- As discussed previously, the base forecast assumes implementation of the Clean Power Plan for reducing greenhouse gas emissions for existing electric power plants, which is currently under legal review. Carbon emissions from energy use are projected to decline slowly, decreasing by an average of 0.2% per year through 2040 because of projected shifts in fuel use from coal to less carbon-intensive fuels (gas and renewables), and because of higher efficiency standards for appliances and commercial equipment, stronger building codes, and higher required mileage from vehicles. Per capita carbon emissions are projected to decline 0.8% per year.

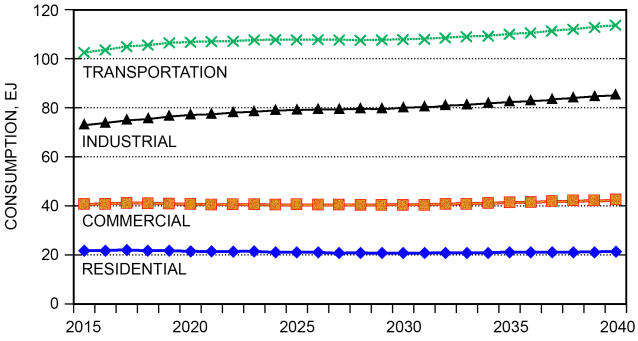

Fig. 16 Projected Total U.S. Energy Consumption by End-Use Sector
(Basis: EIA 2016)

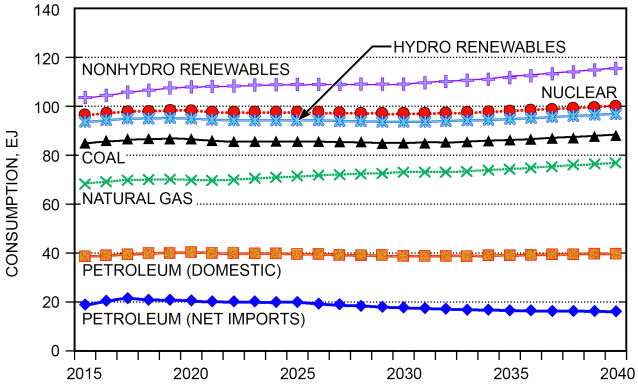

Fig. 17 Projected Total U.S. Energy Consumption by Resource
(Basis: EIA 2016)

- Crude oil prices are expected to rise at an annual rate of 3.9% more than inflation. This high rate of increase is due to a low starting point for crude oil prices in 2015, rather than a fundamental change in projected supply and demand conditions.
- The wellhead price of natural gas was projected to rise at an annual rate of 2.5% more than inflation from 2015 through 2040. However, the starting point is about $2.46/gigajoule wellhead price, well below historic prices of recent years. Natural gas prices are projected to reach $4.74 per gigajoule in 2024, and stay stable near that price until 2040. This forecast assumes a long-term stable price for natural gas, tracking the rate of general inflation, due to abundant supplies of natural gas that result in 20% of United States natural gas production being exported by 2040. For coal used as a fuel, consumption is expected to decrease by 1.6% per year, resulting in a decline of about 40% in consumption compared to 2014 levels. The price of coal used as a fuel is expected to grow at an annual rate of 0.3% more than inflation over the same period. This is less than previous forecasts, and is a result of lower forecasted demand.
- Commercial electricity prices are projected to increase at the rate of inflation over the forecast period to 2040. Lower fuel costs, including increased usage of renewable energy, will be offset by investments in new generation and replacement of aging assets.
- Nuclear power generation is expected to be stable with a 0% growth rate over the forecast period, with construction of new nuclear power plants projected to offset retirements of existing units. Some older nuclear units have applied for a second 20-year life extension permit, which would allow operation for a total of 80 years.

Licensed for single user. © 2021 ASHRAE, Inc.

- Electricity generation using renewable sources (which includes cogenerators) is expected to increase by 3.6% per year. Total renewables, including hydroelectric power, are projected to grow from their current 12% share of electric generation to 25% in 2040.
- Petroleum consumption will grow by 0.2% annually, led by the transportation sector, where most of it (72%) is used.
- The share of petroleum consumption met by net imports is projected to be 41% in 2040, down from 51% in 2015. The U.S. reduction in oil imports is remarkable: as recently as 2005, imports were 60% of liquid fuel use. A steady, slow decline in net imports is expected across the forecast period.
- Natural gas consumption will increase by 0.9% per year in all sectors, driven mostly by increased electric generation using natural gas.
- Coal consumption will decrease at an average annual rate of 1.4%, as coal used for electric generation is replaced by other energy sources.
- Electricity consumption is projected to grow by 0.7% annually, with efficiency gains offset by increased use of electricity-using equipment and an increasing population.
- Total energy consumption in the residential sector is projected to decline by 0.1% per year, and commercial energy consumption is projected to grow by 0.5% per year, as increased efficiency and other factors approximately balance population growth.
- Energy use by the transportation sector is projected to decline by 0.2% per year, with variations from this average depending heavily on prevailing fuel prices. Transportation energy use is declining, which reflects increased fuel efficiency during the forecast period.
- Per capita energy use is projected to decline by 0.2% annually, because increases in efficiency more than offset population growth and new energy-consuming products.
- Total energy use per dollar of gross domestic product (energy intensity) will continue to fall at an average rate of about 1.7% per year through 2040.
- Total carbon emissions are projected to decline by 0.2% annually through 2040, based on current regulations in place, including the Clean Power Plan to restrict electric power sector carbon emissions.

Outlook Summary

In general, the following key issues will dominate energy matters in the next two decades:

- Reduced U.S. dependency on imported oil.
- Increased use of natural gas and renewables, with particularly strong growth in the use of renewables.
- Role of technology developments, including energy conservation and energy efficiency as alternatives to energy production.
- Substantial increases in use of renewable energy, rising from 7.1% of total U.S. production in 2015 to 13.0% in 2040. For electric generation, renewables increase from 12.8% in 2015 to 27.8% by 2040.
- Continued growth in total worldwide carbon emissions, and debate over actions to deal with the issue.
- Relative merits of various energy alternatives, including nuclear power and different renewable energy options.
- Population growth, coupled with the shift of large population segments into retirement.

CHAPTER 35

SUSTAINABILITY

Definition 35.1
Characteristics of Sustainability 35.1
Factors Impacting Sustainability 35.2
Primary HVAC&R Considerations in Sustainable Design 35.2
Factors Driving Sustainability into Design Practice 35.5
Designing for Effective Energy Resource Use 35.8

SUSTAINABILITY is today a goal that just about every organization, institution, business, or individual claims to be striving for, and sometimes claims to have achieved.

Given the profound impact of buildings on the environment, the work of HVAC&R design engineers is inextricably linked to sustainability. The engineering sector has seminal influence on building performance, and HVAC&R designers' work is inherently related to overall sustainability in buildings.

HVAC&R engineering design on projects concerned with performance and sustainability requires understanding of and involvement with more than just HVAC, including projected energy and water demands, stormwater runoff generation, waste generation, and air quality impacts. This chapter is intended to provide key information and identify reference sources for further resources on

- Defining the energy, water, and other resource-consuming aspects of projects
- Quantifying the relative environmental impacts of competing design alternatives

These aspects of sustainability are addressed with respect to energy and water conservation, greenhouse gas and air quality impacts, and other impacts of buildings, such as stormwater runoff and potable water use.

The need to address sustainability in the built environment is being accelerated by external concerns such as environmental and resource issues, rising energy prices, indoor environmental quality, climate change, international pressure, natural disasters, and energy security. While economies transition from carbon-based to other forms of more sustainable energy, engineers will be challenged to meet an ever-increasing tide of regulation, demand, and expectations.

1. DEFINITION

Sustainability is defined in the *ASHRAE GreenGuide* (ASHRAE 2013), in general terms, as "providing for the needs of the present without detracting from the ability to fulfill the needs of the future," a definition very similar to that developed in 1987 by the United Nations' Brundtland Commission (UN 1987). Others have defined sustainability as "the concept of maximizing the effectiveness of resource use while minimizing the impact of that use on the environment" (ASHRAE 2006) and an environment in which "… an equilibrium … exists between human society and stable ecosystems" (Townsend 2006).

Sustaining (i.e., keeping up or prolonging) those elements on which humankind's existence and that of the planet depend, such as energy, the environment, and health, are worthy goals.

The preparation of this chapter is assigned to TC 2.8, Building Environmental Impacts and Sustainability.

2. CHARACTERISTICS OF SUSTAINABILITY

Sustainability Addresses the Future

Sustainability is focused on the distant future. Any actions taken under the name of sustainability must address the impact of present actions on conditions likely to prevail in that future time frame.

In designing the built environment, the emphasis has often been on the present or the near future, usually in the form of capital (or first-cost) impact. As is apparent when life-cycle costing analysis is applied, capital cost assumes less importance the longer the future period under consideration.

This emphasis on the distant future can differentiate sustainable design from **green design**. Whereas green design addresses many of the same characteristics as sustainable design, it may also emphasize near-term impacts such as indoor environmental quality, operation and maintenance features, and meeting current client needs. Thus, green design may focus more on the immediate future (i.e., starting when the building is first constructed and then occupied). Sustainable design is of paramount importance to the global environment in the long term while still incorporating features of green design that focus on the present and near future.

Sustainability Has Many Contributors

Sustainability is not just about energy, carbon emissions, pollution, waste disposal, or population growth. Although these are central ideas in thinking about sustainability, it is an oversimplification to think that addressing one factor, or even any one set of factors, can result in a sustainable future for the planet.

It is likewise a mistake to think that HVAC&R design practitioners, by themselves and just through activities within their purview, can create a sustainable result. To be sure, their activities can *contribute* to sustainability by creating a sustainable building, development, or other related project. But they cannot *by themselves* create global sustainability. Such an endeavor depends on many outside factors that cannot be controlled by HVAC&R engineers; however, they should make their fair-share contribution to sustainability in all their endeavors, and encourage other individuals and entities to do the same.

Sustainability Is Comprehensive

Sustainability has no borders or limits. A good-faith effort to make a project sustainable does not mean that sustainability will be achieved globally. A superb design job on a building with sustainability as a goal will probably not contribute much to the global situation if a significant number of other buildings are not so designed, or if the transportation sector makes an inadequate contribution, or if only a few regions of the world do their fair share toward making the planet sustainable. A truly sustainable outcome thus depends on comprehensive efforts in all sectors the world around.

Technology Plays Only a Partial Role

It may well be that in due time technology will have the theoretical *capability*, if diligently applied, to create a sustainable future for the planet and humankind. Having the capability to apply technology, however, does not guarantee that it will be applied; that must come from attitude or mindset. As with all things related to comprehensive change, there must be the *will.*

For example, automobile companies have long had the technical capability to make cars much more efficient; some developed countries highly dependent on imported oil have brought their transportation sectors close to self sufficiency. Until recently, that has not been the case in the United States. Part of the change is because of increased customer demand, but more of it is driven by government regulation (efficiency standards). The technology is available, but the will is not there; large-scale motivation is absent, what exists being mostly driven by regulation and the motivated few.

Similarly, HVAC&R designers know how to design buildings that are much more energy efficient than they have been in the past, but such buildings are still relatively rare, especially in the general commercial market (as opposed to those owned by high-profile entities). ASHRAE's long-standing guidance in designing energy-efficient (now green and/or sustainable) buildings, and the motivation provided by its own and other entities' programs, have pointed the way technologically for the built environment and related industries to make their fair-share contribution to sustainability. Such programs include (1) ASHRAE's net-zero energy buildings (NZEB) thrust; (2) the U.S. Green Building Council's (USGBC) Leadership in Energy and Environmental Design (LEED®) Green Building Rating System™; (3) the American Institute of Architects' (AIA) 2030 Challenge (AIA 2011); (4) the Green Building Institute's (GBI) Green Globes (www.thegbi.org/greenglobes); and (5) the U.S. Environmental Protection Agency's (EPA) ENERGY STAR® program (www.energystar.gov/). The European Union (E.U.) has also taken a lead in the fight against climate change and promoting a low-carbon economy, although unsustainable trends persist in many areas.

ASHRAE's mission "to advance the arts and sciences of HVAC&R to serve humanity and promote a sustainable world" and its vision to "be the global leader, [and] the foremost source of technical and educational information" (www.ashrae.org/about-ashrae) has already had significant impact. However, more can be done, both within its technological purview and in overcoming other, nontechnological barriers. ASHRAE has set a good example in its area of expertise and can also encourage, advise, and inspire other sectors to do their part to move towards sustainability. Examples include ASHRAE's guidance provided to the U.S. government on effective building energy efficiency programs, as well as its many publications such as the *Advanced Energy Design Guides* (AEDGs), the *ASHRAE GreenGuide*, and its numerous standards and guidelines.

3. FACTORS IMPACTING SUSTAINABILITY

The major factors impacting global sustainability are the following:

- Population growth and migration
- Food supply
- Disease control and amelioration
- Energy resource availability
- Material resource availability and management
- Fresh water supply, both potable and nonpotable
- Effective and efficient usage practices for energy resources and water
- Air and water pollution
- Solid and liquid waste disposal
- Land use

The preceding are only broad categories, yet they encompass many subsidiary factors that have received public attention recently. For instance, climate change/global warming, carbon emissions, acid rain, deforestation, transportation, and watershed management are important factors as well. However, each of these can be viewed as a subset of one or more of the listed major areas.

4. PRIMARY HVAC&R CONSIDERATIONS IN SUSTAINABLE DESIGN

The main areas falling within an HVAC&R designer's (and ASHRAE's) purview on most projects are those dealing with energy and water use, material resources, air and water pollution, and solid waste disposal. Although HVAC&R professionals' expertise may impact issues such as land use and food supply on certain specialized projects, these more typically fall under the purview of other professionals and their organizations.

Energy Resource Availability

Although conventional energy resources and their availability largely fall beyond the scope of HVAC&R designers' work, an understanding of these topics is often required for participation in project discussions or utility programs relating to projects. Chapter 34 has more information on energy resources.

Some **renewable** energy resources, in contrast with traditional energy and fuels, are ubiquitous by nature and are thus available on many building sites. **Wind** and **solar** energy are widely distributed (if not always continuously available) on almost any site for use in active or passive ways. Chapter 35 of the 2019 *ASHRAE Handbook—HVAC Applications* and Chapter 37 of the 2020 *ASHRAE Handbook—Systems and Equipment* provide information on solar energy resources, passive and active space heating and cooling, domestic hot water, and applications of photovoltaics. High-level (high-temperature) **geothermal** energy is only present at limited sites, and may thus be unavailable as a direct energy source on most projects. Low-level geothermal, on the other hand, depends on the nearly constant temperature of the near-surface earth for use as an energy source or sink, and thus can be used on almost any project if other factors align in its favor. See Chapter 34 of the 2019 *ASHRAE Handbook—HVAC Applications* for more information.

Climatic conditions may often provide another source of "renewable" energy. In arid climates, air systems using evaporative cooling (both direct and indirect) can supplement conventionally powered cooling and refrigeration systems.

Designers should be familiar with the characteristics of common traditional (nonrenewable) energy resources (natural gas, heating oil, electricity) from the standpoint of their use in relevant building applications. Designers are typically very familiar with the relative per-unit cost as it affects the operating cost of the building being designed. Other energy characteristics traditionally taken into account by the designer might also include ease of handling and use, cleanliness, emissions produced, and local availability, because these also have a direct effect on design and installation. Until recently, designers had little reason to consider an energy resource's characteristics beyond the site line of the project at hand.

However, recent public focus on the impacts of building energy use on the environment has changed that approach. Designers now must consider a resource's broader characteristics that may affect the regional, national, and global environment, such as its origin (domestic or foreign), security, future availability, emissions characteristics, broad economics, generation/use limitations [gravimetric energy density (J/kg) and areal power density (W/m^2)] and social acceptability. Though responsible designers may not be able to do much about such factors, they should be aware of them; indeed, that awareness may affect decisions within the designer's control.

Licensed for single user. © 2021 ASHRAE, Inc.

For instance, familiarity with an energy resource's emissions characteristics, whether at the well head, mine mouth, or generating station, may influence the designer to make the building more energy efficient, or provide the designer with arguments to convince the owner that energy-saving features in the building would be worth additional capital cost. Furthermore, as owners and developers of buildings become more aware of sustainability factors, designers must stay informed of the latest information and impacts.

One way to reduce a project's use of nonrenewable energy, beyond energy-efficient design itself, is to replace such energy use with renewable energy. Designers should develop familiarity with how projects might incorporate and benefit from renewable energy. Many kinds of passive design features can take advantage of naturally occurring energy.

Increasingly common examples of nonpassive approaches are solar systems, whether photovoltaic (electricity-generating) or solar thermal (hot-fluid generating). Low-level geothermal systems take advantage of naturally occurring and widely distributed earth-embedded energy. Wind systems are increasingly applied to supplement electric power grids, and are also sometimes incorporated on a smaller scale into on-site or distributed generation approaches.

Some large power users, such as municipalities or large industries, require that a minimum percentage of power they purchase be from renewable sources. Also, renewable portfolio standards are being imposed on electric utility companies by regulators.

Fresh Water Supply

HVAC&R systems can impact potable and nonpotable water supplies both directly and indirectly. First, some building systems (e.g., evaporative cooling towers) use potable water. Second, some building systems can discharge treated water or other waste streams with contaminants of concern that can impact local watersheds and water supplies. Indirect impacts include water consumption for electricity generation and in mineral and fuel extraction.

Effective and Efficient Use of Energy Resources and Water

This area is where HVAC&R engineers can have a profound impact on achieving sustainability goals. Impacts of building consumption can be at least partially mitigated through overall system performance improvement, as well as through increased use of on-site renewable energy and certain off-site energy resources. See the section on Designing for Effective Energy Resource Use for more information on addressing energy efficiency in the design process.

Water Consumption. Building systems' water use can be reduced by reusing clean water from on site, such as condensate drain water, or by using less potable water. For example, hybrid cooling towers can operate as water-to-air heat exchangers when run dry, and can operate their water sprays for additional evaporative capacity only when conditions require. (See also the section on Energy Resource Availability.) In process control and refrigeration systems, similar opportunities exist.

The U.S. EPA's WaterSense program (www3.epa.gov/watersense/) rates products on their water use efficiency; similarly to the EPA's ENERGY STAR program, products are certified by an outside third party before they can claim the WaterSense label. ASHRAE is also developing a standard to provide minimum requirements for the design of mechanical systems that limit the volume of water required to operate HVAC systems (*Proposed Standard* 191P).

In Europe, the U.K. *Building Regulations* (U.K. 2015) requires that design water consumption be reduced in new homes, with a combined hot- and cold-water consumption of no more than 125 L per person per day of potable water. Alternative sources of lower-grade water, such as harvested rainwater and reclaimed gray water, may also be used for functions such as toilet flushing, subject to specific measures. The 2015 edition introduced an optional requirement of 110 L per person per day where required by planning permission, and an alternative fittings-based approach to demonstrating compliance instead of the prescribed calculation method.

Discharge from building systems can be reduced through careful design, proper sequences and control, and choosing lower-impact chemical or nonchemical water treatment. These techniques may not eliminate chemical treatment in all applications, but negative effects from such usage can be substantially reduced.

Water/Energy Nexus. The water/energy nexus refers to the interdependent and inseparable nature of these two important resources. From large-scale utilities to the built environment, water production requires energy to extract and deliver for consumption, and electricity generation and energy sources (e.g., thermal and nuclear power generation, hydraulic fracturing, biofuels) demand significant amounts of water for production. With approximately 8% of the global energy generation used for pumping, treatment, and transportation of water resources and approximately 15% of the world's total water withdrawal used for energy production, each resource will continue to face rising demands and constraints as a consequence of economic and population growth and climate change.

Increasing energy demands, as well as naturally occurring water constraints such as droughts, heat waves, or human-induced shortages, mean that demands on water resources can be expected to increase. In addition, changing temperatures, shifting precipitation patterns, increasing variability, and more extreme weather add significant uncertainty about water availability. Water and energy, in their various classifications, are generally viewed in individual silos, which has limited adoption of integrated solutions. To properly address the challenges and opportunities around the water/energy nexus, emphasis on policy incentives and sustainable engineering solutions promoting optimized, efficient use of each resource, as well as advancement in technologies promoting both water and energy conservation, are needed.

Material Resource Availability and Management

Environmentally conscious design and construction practices are increasingly motivating design teams to apply life-cycle thinking and look in to the embodied impacts (e.g., embodied energy, embodied CO_2, other equivalent environmental impact indicators) of their systems' design, although this is not yet a common practice. For example, within the LEED framework, building systems under the purview of HVAC&R designers are currently excluded from credits for locally procured building materials and resources. However, the same concepts can be applied in selection and procurement of HVAC&R system components. For example, recycled steel content in system components could be required to be stated in HVAC&R product submittals. In some areas, locally assembled or manufactured components may be available that can reduce transportation impacts.

Embodied Energy

As buildings become more energy efficient and their operational energy is reduced, more emphasis will shift toward reducing their embodied energy (UNEP 2014). Materials used directly in the construction and the components, equipment, and systems for building operation embody the energy used during their manufacturing, transportation, and installation (ASHRAE 2013). Material selection should also consider the environmental impact of demolition and disposal after the service life of the products. Building **life-cycle assessment (LCA)** focuses on the environmental impact of a product system (from materials acquisition to manufacturing, use, and final disposition) and plays a major role in promoting sustainability. This is a cradle-to-grave approach that evaluates all stages of individual materials and the product's life to determine their cumulative

Licensed for single user. © 2021 ASHRAE, Inc.

environmental impact. Srinivasan et al. (2014) reviews various building assessment methods that support environmental decision making. Designers should give preference to resource-efficient materials and reduce waste by recycling and reusing whenever possible.

LCA is an internationally standardized methodology (ISO *Standard* 14040). Consecutive parts of an LCA include a life-cycle inventory (e.g., collection and analysis of air and water emissions, waste generation, and resource consumption over the product's life cycle) and life-cycle impact assessment (LCIA), which is an estimation of indicators of the environmental pressures in terms of climate change, summer smog, resource depletion, acidification, human health effects, etc., attributable to the product's life cycle. More information on the LCA approach is available online from the EPA (www.epa.gov/saferchoice/design-environment-life-cycle-assessments) and the European Commission (ec.europa.eu/environment/ipp/lca.htm). Various LCA databases and tools available from commercial as well as governmental or public domain sources can be used to calculate and compare the embodied energy (e.g., total energy per unit mass), related embodied emissions (e.g., total mass of CO_2 per unit mass of material or product), or other embodied environmental impacts of common building materials and products.

A challenge for modeling life-cycle energy use in buildings is using consistent system boundaries and data collection (Srinivasan et al. 2014). Available software to address these concerns includes Building for Environmental and Economic Sustainability (BEES; www.nist.gov/services-resources/software/bees) and the Tool for Reduction and Assessment of Chemicals and Other Environmental Impacts (TRACI), which focus on chemical releases and raw materials usage in products. The Athena Sustainable Materials Institute's decision support tool provides a cradle-to-grave, process-based LCA, including regional data such as energy mix for power generation, transportation modes, etc. (www.athenasmi.org/what-we-do/lca-data-software/). Regional data are important because conversion factors to primary energy and GHG emissions can differ by country, depending on energy sources used (e.g., coal- or oil-fired power plants versus solar or natural-gas-based generation).

LCA-based information may be in the form of environmental product declarations (EPD) based on CEN *Standard* 15804, or product environmental footprints (PEFs) inspired by ISO *Standards* 14040 and 14044 and voluntary environmental declarations (ISO *Standard* 14025). They have been gaining in popularity beyond building construction materials, given the growing criteria of green building certifications such as LEED v4 credit, which now rewards selection of HVAC products with EPDs, based on the updated LEED credit interpretation in early 2015. Another example is the French EPD program and national decree that regulates EPDs for construction products, which will also address HVAC equipment and other technical installations by mid-2017 (Passer et al. 2015).

LCA can also assess specific refurbishments intended to improve energy performance of systems in existing buildings. For example, replacing electric or gas water heaters with solar hot-water systems can provide net emissions savings compared with the conventional systems after 0.6 month to 2.5 years, depending on the auxiliary fuel (Crawford et al. 2003). For solar domestic hot-water systems and solar central space heating, the energy consumed by producing and installing the solar systems is recovered in about 1.2 years, and the payback time for the systems' embodied energy emissions varies from a few months (for solar domestic water heating) to 9.5 years (for solar central space heating), again depending on the energy carrier for the conventional system and the specific environmental emission indicators considered (Kalogirou 2004).

Air, Noise, and Water Pollution

HVAC&R systems and equipment can interact with both local and global environments. On a local scale, HVAC&R systems interact with the environment in ways such as acoustical noise generated by heat rejecting equipment (e.g., condensing units, cooling tower). Occasionally, this may require the addition of special barriers to prevent sound migration from the site, as shown in Figure 1.

Local impacts of combustion from on-site heat or electricity generation can be mitigated to an extent through careful consideration of the location of sources (emitters) with respect to nearby receptors, including outdoor air intakes and residences or other buildings with operable windows.

On a larger scale, air and water pollution occurs indirectly through the consumption of energy to operate building systems. This occurs in generating the electricity (whether from fossil fuel, nuclear, or hydroelectric resources), steam, or hot water for building heating or cooling. In this sense, improved efficiency is an approach to partial mitigation.

Solid and Liquid Waste Disposal

The solid waste disposal burden from installation and operations of building systems can be substantially reduced. Competing alternatives can be assessed through life-cycle analysis. For example, an air-cooled unitary system with a shorter service life than a costlier water-cooled alternative could, over the course of the building's life, increase the solid waste burden when it is discarded. Reuse options should also be considered for locally available materials or process by-products.

An example of an HVAC&R design impacting liquid waste disposal is using glycol to protect coils from freezing, where the glycol must be eliminated in summer to provide required capacity. Because reusing glycol is not a common practice, such a design would likely result in an annual glycol discharge.

In many locations, water quality regulations and agencies essentially limit or prohibit liquid waste disposal. Other approaches to pursue in reducing liquid waste disposal are discussed in the section on Effective and Efficient Use of Energy Resources and Water.

5. FACTORS DRIVING SUSTAINABILITY INTO DESIGN PRACTICE

HVAC&R designers face many challenges as they assimilate sustainability into their engineering practices. These challenges include climate change, a fast-changing regulatory and legal environment, and evolving standards of care. New tools, technologies, and approaches are required for well-prepared HVAC&R engineers. The challenges and the responses are creating new opportunities, just as changing project processes are allowing or requiring engineers to participate in projects in new ways.

Climate Change

In addition to their causal role, energy systems are exposed to significant vulnerabilities resulting from climate change (Bruckner et al. 2014). Increased volatility in weather profoundly affects HVAC&R practice. Historical weather data and extremes may inadequately describe conditions faced by a project built today, even over a modest building lifespan.

In 1988, the United Nations Environment Programme (UNEP) and the World Meteorological Organization (WMO) established the Intergovernmental Panel on Climate Change (IPCC) (www.ipcc.ch) to study and report on the scientific issues, potential impacts, and mitigation methods associated with climate change. A series of publications discusses the possible outcomes and interventions required to mitigate the impacts of anthropogenic emissions.

During the United Nations Framework Convention on Climate Change in Paris, 195 nations reached a historic agreement to combat climate change and encourage actions and investment toward a low-carbon, resilient, and sustainable future (UNFCC 2015); the agreement governs greenhouse gas emissions measures from 2020 and limits average global warming to 2 K above preindustrial temperatures, while striving for a limit of 1.5 K. It also aims to strengthen the ability to deal with the impacts of climate change. Crucial areas include

- Mitigation: reducing emissions quickly enough to achieve the temperature goal
- Transparency system and global stock-taking: accounting for climate action
- Adaptation: strengthening countries' ability to deal with climate impacts
- Loss and damage: strengthening ability to recover from climate impacts
- Support (including financial support): for nations to build clean, resilient futures (e.g., work to define a clear roadmap on ratcheting up climate finance to USD 100 billion by 2020 for developing nations)

The agreement will come into force after 55 countries that account for at least 55% of global emissions have deposited their instruments of ratification. Accordingly, each country should set up a bottom-up system, setting its own goals for nationally determined contribution and a coherent plan for reaching these objectives. Starting in 2018, each country will have to increase their pledges over time and submit new plans every five years. (See also the discussion in the section on Regulatory Environment.)

Responsible designers are concerned with multiple dimensions of climate change: not only *what* they can do to reduce their designs' contribution, but also *whether* and *how* their designs should anticipate the future. It is the first that is the focus of this chapter and a majority of the available information on sustainable design. Warming trends currently occurring have been observed with certainty. As a result, historical weather data may not be the best source for load calculations. Depending on the rate of change, anticipating future weather may become more significant in its impact on the climate control of building systems.

Responsible designers are concerned with two dimensions of climate change: not only *what* they can do to reduce their designs' contribution, but also *whether* and *how* their designs should anticipate the future. It is the first that is the focus of this chapter and a majority of the available information on sustainable design. Warming trends currently occurring have been observed with certainty. As a result, historical weather data may not be the best source for load calculations. Depending on the rate of change, anticipating future weather may become more significant in its impact on the climate control of building systems.

Regulatory Environment

The global community has responded to two major environmental issues during the past two decades. In the late 1980s, the Montreal Protocol (UNEP 2003) regulated the manufacture and trade of refrigerants that had been shown to damage the stratosphere by depleting stratospheric ozone. The effect on the HVAC&R industry was to require research and investment in alternative materials to those that had become the mainstays of the industry, as shown in Figure 2.

Next, in the early 1990s, came the much more controversial issue of greenhouse gas (GHG) emissions and their potential for causing global warming. In response to these threats, some countries signed and accepted the Kyoto Protocol (UNFCCC 1998), which placed future limits on these emissions, but most large-emitter countries did not. By 2011, when follow-up climate talks occurred in Durban, South Africa, overall global GHG emissions not only had not been reduced but had increased. No new GHG emission reduction targets came out of those talks, although the countries agreed to look at the limits issue again in 2020 and to set up a "green fund" to help poor nations deal with climate change.

Despite the lack of effective global action, evidence of climate change is compelling. The Synthesis Report that integrated the findings of the three working group contributions to the Fifth Assessment Report of the Intergovernmental Panel on Climate Change (IPCC 2014) confirmed that "human influence on the climate system is clear and growing, with impacts observed across all continents and oceans. . . . Many of the observed changes since the 1950s are unprecedented over decades to millennia. The IPCC is now 95% certain that humans are the main cause of current global warming." Similar conclusions have also been supported by the National Academy of Sciences (NAS 2010), which concluded that "Climate change is occurring, is caused largely by human activities, and poses significant risk for—and in many cases is already affecting—a broad range of human and natural systems."

The predominant greenhouse gas pollutant is carbon dioxide, which is mainly a by-product of fossil fuel combustion in the

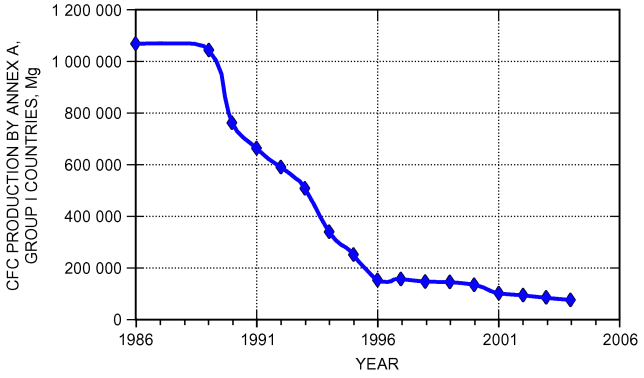

Fig. 2 Effect of Montreal Protocol on Global Chlorofluorocarbon (CFC) Production

Licensed for single user. © 2021 ASHRAE, Inc.

transportation, power, industrial, residential, and commercial sectors. According to the EPA (2016), CO_2 contributed about 82% of total U.S. emissions in 2013. Methane is the next highest contributor, accounting for about 10% of the total U.S. emissions. Sources of methane emissions include oil and gas systems, enteric fermentation, landfills, coal mines, etc. Nitrous oxide (N_2O) and fluorocarbon gases are other contributors to GHG emissions. In 2014, the top four emitting countries/regions, accounting for almost two-thirds (61%) of the total global CO_2 emissions, are China (30%), the United States (15%), the 28 E.U. Member States (10%), and India (6.5%). On a per capita basis, emissions in the United States (16.5 tonnes CO_2 per capita) are twice as high as those of China (7.6) and the European Union (6.7) (Olivier et al. 2015).

Various standards, policies, and regulations under way that target reduction of U.S. GHGs in various sectors: examples include state renewable portfolio standards (RPS) programs, corporate average fuel economy (CAFE) standards, state emission performance standards for power plants [e.g., California (2006) *Senate Bill* SB 1368], and cap-and-trade programs in the Regional Greenhouse Gas Initiative (RGGI; www.rggi.org) states and California.

In the United States, a consolidation of green building codes is planned: the merger of ASHRAE *Standard* 189.1 and ICC's *International Green Construction Code* (see also the section on Evolving Standards of Care) is on track to occur in 2018. Energy efficiency levels in U.S. codes will continue to improve, with the green building codes evolving toward a net energy intensity level that, by 2025, is 20 to 25% of the code minimums that existed at the turn of the 21st century.

Under its 2020 strategy, the E.U. has committed to an ambitious plan and introduced binding legislation for the E.U. Member States to meet three climate and energy targets by the end of 2020: (1) 20% cut in GHG emissions from 1990 levels, (2) obtain 20% of E.U. energy from renewables, and (3) 20% improvement in energy efficiency (ec.europa.eu/clima/policies/strategies/index_en.htm). The E.U. emissions trading system (E.U. ETS) is a cornerstone of the policy to combat climate change and a key tool for reducing industrial GHG cost effectively. The ETS covers more than 11 000 power stations and industrial plants in 31 countries, as well as airlines, and accounts for about 55% of total E.U. emissions. For sectors not in the ETS, the E.U. Member States have taken on binding annual targets until 2020 for cutting emissions under the effort-sharing decision (between 2013 and 2020) according to national wealth, measured by gross domestic product per capita; these targets range from a 20% cut for the richest countries (e.g., Luxembourg, Denmark) to a maximum 20% increase for the least wealthy (e.g., Bulgaria). Moreover, a new E.U. framework has set three key targets for 2030: (1) at least 40% cuts in GHG, (2) at least 27% share for renewable energy, and (3) at least 27% improvement in energy efficiency. The 2050 roadmap suggests that the E.U. should cut emissions to 80 to 95% below 1990 levels.

Evolving Standards of Care

This section is based on Lawrence et al. (2016).

Litigation relating to sustainability and global climate issues has increased. For example, a consortium of states successfully sued, and the U.S. Supreme Court agreed in 2007, that the U.S. EPA may act to consider CO_2 a pollutant that is harming the environment and thus take measures to regulate its emissions. This ruling is one of several developments in the continued and broadened response to CO_2 emissions by society at large. Building design and construction industries are already being impacted.

Sustainability is being adopted into building codes at different levels of government and with varying motivation. Different approaches reflect local societal perceptions, political priorities, national policies and economic factors [see, e.g., Lawrence et al. (2016) and references therein for an overview of current status and trends of sustainable building codes adopted in the United States and the E.U.].

U.S. Initiatives. In the United States, a combination of methods and programs have gradually increased focus on sustainability in new commercial and residential construction. The methods range from voluntary programs (including rating systems and guidelines) to standards and mandatory enforceable codes. One early voluntary program was **U.S. Green Building Council's Leadership in Energy and Environmental Design (USGCB's LEED),** which was at the forefront of including sustainable design practices in building codes worldwide. LEED ratings can be applied to a wide variety of building types and aspects (e.g., interior design and construction, neighborhood development, operations and maintenance); see www.usgbc.org/resources/grid/leed for specific ratings systems. At least 16 U.S. states now require LEED Silver certification for public buildings, and in most states some level of LEED certification is a required option for state buildings.

Most states' building codes follow the **International Green Construction Code™ (IgCC™)** for sustainability guidance. One of IgCC's compliance options involves following ASHRAE *Standard* 189.1's mandatory criteria in all topical areas (e.g., site, construction, materials, energy, indoor environmental quality, water).

In 2010, California adopted its own statewide green buildings code, **CALGreen,** an updated version of which came into effect January 2014 (CALGreen 2013). Unlike most other U.S. codes, this approach includes criteria for both residential and nonresidential buildings in the same program.

ASHRAE's **Building Energy Quotient® (Building EQ®**; www.buildingenergyquotient.org/) focuses on lowering building operating cost and increasing value. Both as-designed and in-operation energy use ratings are available.

As with green building codes, cities are beginning to require energy reporting and benchmarking for commercial buildings. As of early 2016, 14 major cities (Atlanta, Austin, Berkeley, Boston, Boulder, Cambridge, Chicago, Kansas City, New York, Philadelphia, Portland, San Francisco, Seattle, and Washington, D.C.) had adopted some form of energy reporting in local ordinances, although the size and type of buildings involved may differ. The motivation for these requirements is usually increasing overall citywide energy efficiency, as well as creating local energy auditing jobs.

E.U. Initiatives. Outside the United States, the most notable voluntary program is the **BREEAM** method (www.breeam.com), an environmental assessment method and rating system introduced in the U.K. in 1990. This is a consensus-based, market-oriented assessment and sustainability benchmarking program for any type of building or large-scale community worldwide. It has one mandatory assessment area (the building's potential environmental impact) and two optional assessment areas (design process, and operation/maintenance). Over 425,000 buildings have been certified. Specific national schemes are available in Germany, Norway, Sweden, Spain, and The Netherlands.

Another U.K. rating system is the **Global Environmental Method (GEM)** (www.greenglobes.com/existing/homeuk.asp), which is a version of the U.S. and Canadian program Green Globes (www.greenglobes.com).

In Germany, the **passive house** concept has evolved to an international association for standardizing the design and construction of low-energy buildings (passiv.de/en/). Similar approaches and labels, especially for residential buildings, are also used in France (e.g., **Effinergie**) and Switzerland (e.g., **Minergie**).

European regulatory efforts have also introduced several mandatory directives towards sustainability at all stages of the energy chain, targeting the buildings sector that plays a major role. The European Union's Sustainable Development Strategy (SDS)

Licensed for single user. © 2021 ASHRAE, Inc.

(ec.europa.eu/environment/eussd/index.htm) addresses climate change and clean energy, sustainable consumption and production, conservation and management of natural resources, public health, social inclusion, global poverty and sustainable development challenges, and education and training. The main E.U. sustainable consumption and production (ESCP) initiatives support efforts to meet the goals of SDS (ec.europa.eu/environment/eussd/escp_en.htm) and build on international and E.U.-wide initiatives and tools [e.g., the United Nations' Marrakech Process (esa.un.org/marrakechprocess/index.shtml)]. Beyond operational energy issues for sustainable buildings, E.U. ESCP policy focuses on resources such as materials (including waste), water, and embodied energy. The E.U. Waste Framework Directive (WFD; E.U. *Directive* 2008/98/EC) aims for 70% for reuse, recycling, and others forms of material recovery (excluding energy recovery), and is the main European policy driver toward better recycling of construction and demolition waste. The WFD is expected to reduce burdens on the waste stream, because construction and demolition waste (CDW) accounts for 25 to 30% of the waste generated in Europe. CDW has a high potential for recycling and reuse, averaging about 46% across Europe (depending on value of the materials and availability of well-developed technology and infrastructure) (Dodd et al. 2015).

Energy efficiency can be increased at all stages of the energy chain, from generation to consumption (ec.europa.eu/energy/en/topics/energy-efficiency). The main European legislative tool for improving buildings' energy efficiency and reducing carbon emissions is the Energy Performance of Buildings Directive (EPBD; E.U. *Directive* 2010/31/EC): E.U. Member States must apply minimum energy performance requirements on all new and existing residential and nonresidential buildings when undergoing major renovation (25% of building surface or value). The EPBD requires that all new buildings must be nearly zero energy as of January 2021; new buildings occupied or owned by public authorities must comply as of January 2019. Other major policies include

- Renewable Energy Directive (RED; E.U. *Directive* 2009/28/EC), which establishes an overall policy for the production and promotion of energy from renewables
- Ecodesign (ED; E.U. *Directive* 2009/125/EC) and Energy Labelling Directives (ELD; E.U. *Directive* 2010/30/E.U.), which establish minimum energy efficiency standards for various products (including air-conditioners, boilers, circulators, motors, fans, pumps)
- Energy Efficiency Directive (EED; E.U. *Directive* 2012/27/E.U.), which establishes a common framework for promotion of energy efficiency, and sets energy savings requirements for buildings

In accordance with the EPBD, energy performance certification (EPC) of European buildings is an ongoing process for several years; see ASHRAE (2013) for examples. EPCs document the building's energy performance, usually using an easy-to-understand indicator expressed as a ranking energy label (building class) with an index in terms of primary or final energy use, carbon dioxide emissions, or energy cost per unit of conditioned floor area. EPCs also may include an assessment of indoor environmental quality. In January 2013, The Netherlands became the first E.U. Member State to require measurement of GHG in buildings (Dodd et al. 2015): the Dutch Building Decree requires reporting of GHG emissions and depletion of natural resources for structural components of residential and office buildings (over 100 m^2) on application for a building permit.

Changing Design Process

Even in jurisdictions without regulatory action, change is happening in the HVAC&R industry. Today's engineer can contribute value to projects that have sustainability goals, using some of the many resources and approaches cited in this chapter. (See the section on Designing for Effective Energy Resource Use.)

ASHRAE, in partnership with the Illuminating Engineering Society (IES) and USGBC, developed *Standard* 189.1 for high-performance green buildings, which calls for a determination of annual CO_2 equivalent emissions in addition to overall energy savings and other requirements. The component of such emissions from electricity use depends on the mix of fuels used to generate that electricity. In addition to regional variations, the overall fuel mix is projected to change, as shown in Figure 3.

Emissions considerations alone are not the only driver for design decision making. Energy prices and societal pressures continue to mount. Examples of recent drivers include

- Antiquated electric transmission and distribution infrastructure and plans to develop a smart grid to improve it
- Power plants being forced to become cleaner and more efficient, expediting closure of cheap, dirty generators
- Mandates imposed on utilities to provide more renewable energy to customers
- Influence of commodities trading markets on spot and future prices
- Constrained natural gas reserves and growth in demand continuing to increase volatility in the natural gas market
- Climate change, through environmental pressures to reduce carbon emissions in the face of increased demand for electricity, and infrastructure damage from more frequent storms
- Growing impatience from some elements, both domestically and internationally, over the perceived slow pace of acceptance of sustainable design, leading proponents to push harder for seriously addressing climate and energy resource issues

These and other pressures are changing project teams and their work; those teams are being asked to

- Incorporate sustainable design guidance, standards, and rating systems into their work
- Add a variety of new team members to bring additional expertise to address sustainability
- Gather quantitative data related to energy, water, occupant satisfaction, greenhouse gas emissions, etc.
- Use new analysis tools (e.g., daylighting modeling) to help maximize sustainability

Opportunities relating to sustainability for the well-prepared engineer are growing. The increased focus on sustainability in the built environment allows for more integrated, effective, and efficient ways to meet the nexus between environment, economy, regulation, and societal pressure. The challenge for the industry is how quickly

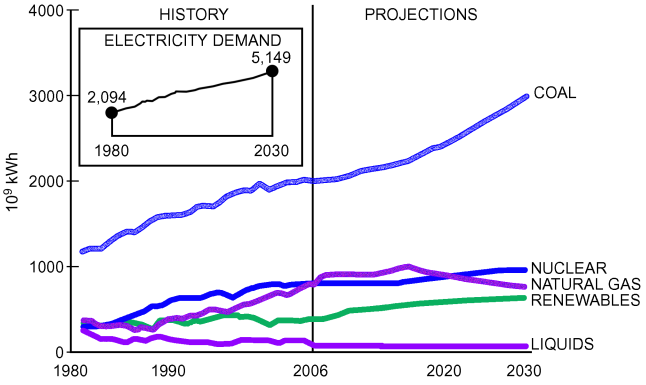

Fig. 3 Electricity Generation by Fuel, 1980–2030
(EIA 2008)

Licensed for single user. © 2021 ASHRAE, Inc.

it can adapt to these new opportunities and grow in an increasingly regulated environment. At the very least, the standard of care for engineers must be tracked and implemented to manage liability. Sustainability can provide an opportunity for engineers and others to increase market share while exceeding current regulatory constraints and anticipating future regulations. More details on design considerations are provided in the section on Designing for Effective Energy Resource Use.

Integrating sustainability into HVAC&R system design can result in built environments that respect the greater environment and provide safe and comfortable indoor environments. The three occurrences of the letter *i* in *sustainability* can be thought of as representing key concepts in sustainable design: *interactive*, *iterative*, and *integrated*. Design processes that require greater *interaction* between team members and more *iterative* analysis to improve design solutions can be undertaken by teams through what has become known as *integrated* design.

Sustainability is inherently multidisciplinary. Recognizing this, teams often assemble a broad array of experts in a collaborative, interdisciplinary approach to achieve the highest levels of sustainability possible. This integrated design approach is addressed in Chapter 58 of the 2019 *ASHRAE Handbook—HVAC Applications* and in ASHRAE (2013).

Other Opportunities

In addition to designing HVAC&R systems, engineers may increasingly be called upon to help address issues ranging from transportation to irrigation to on-site renewable energy. The approach to sustainable design alternatives opens the door for creativity and innovation in the design process. Rather than taking a one-size-fits-all approach to design, engineers can provide a range of available solutions and facilitate flexible implementation. Often, engineers are asked to develop and evaluate measures based on both economic and environmental performance. Success may require several design iterations to achieve the desired performance.

6. DESIGNING FOR EFFECTIVE ENERGY RESOURCE USE

Most energy used in buildings is from nonrenewable resources, the cost of which historically has not considered replenishment or environmental impact. Thus, consideration of energy use in design has been based primarily on economic advantages, which are weighted to encourage more rather than less use.

As resources become less readily available and more exotic, and replenishable sources are investigated, the need to operate buildings effectively using less energy becomes paramount. Extensive studies since the mid-1970s [see, e.g., Doris et al. (2009) and references therein] have shown that building energy use can be significantly reduced by applying the fundamental principles discussed in the following sections.

Energy Ethic: Resource Conservation Design Principles

The basic approach to energy-efficient design is reducing loads (power), improving transport systems, and providing efficient components and "intelligent" controls. Important design concepts include understanding the relationship between energy and power, maintaining simplicity, using self-imposed budgets, and applying energy-smart design practices.

Energy and Power

From an economic standpoint, more energy-efficient systems need not be more expensive than less efficient systems. Quite the opposite is true because of the simple relationship between energy and power, in which power is simply the time rate of energy use (or, conversely, energy is power times time). Power terms such as kilowatts are used in expressing the size of a motor, chiller, boiler, or transformer. Generally, the smaller the equipment, the less it costs. Other things being equal, as smaller equipment operates over time, it consumes less energy. Thus, in designing for energy efficiency, the first objective is always to reduce the power required to the bare minimum necessary to provide the desired performance, starting with the building's heating and cooling loads (a power term, in kilowatts) and continuing with the various systems and subsystems.

Simplicity

Complex designs to save energy seldom function in the manner intended unless the systems are continually managed and operated by technically skilled individuals. Experience has shown that long-term, energy-efficient performance with a complex system is seldom achievable. Further, when complex systems are operated by minimally skilled individuals, both energy efficiency and performance suffer. Most techniques discussed in this chapter can be implemented with great simplicity.

Self-Imposed Budgets

Just as an engineer must work to a cost budget with most designs, self-imposed power budgets can be similarly helpful in achieving energy-efficient design. The *Advanced Energy Design Guide* series from ASHRAE are a source for guidance on achievable design budgets. For example, the following are possible categories of power (or power-affecting) design budgets for a mid-rise office building:

- Installed lighting (overall) W/m^2
- Space sensible cooling W/m^2
- Space heating load W/m^2
- Electric power (overall) W/m^2
- Thermal power (overall) W/m^2
- Hydronic system head kPa
- Water chiller (water-cooled) kW/kW cooling (COP)
- Chilled-water system auxiliaries kW/kW cooling
- Unitary air-conditioning systems kW/kW cooling (COP)
- Annual electric energy $MJ/(m^2 \cdot yr)$
- Annual thermal energy $kJ/(m^2 \cdot yr \cdot K \cdot day)$

As the building and systems are designed, all decisions become interactive as each subsystem's power or energy performance is continually compared to the budget.

Design Process for Energy-Efficient Projects

Consider energy efficiency at the beginning of the building design process, because energy-efficient features are most easily and effectively incorporated at that time. Seek the active participation of all members of the design team, including the owner, architect, engineer, and often the contractor, early in the design process. Consider building attributes such as building function, form, orientation, window/wall ratio, and HVAC system types early in the process, because each has major energy implications. Identify meaningful energy performance benchmarks suited to the project, and set project-specific goals. Energy benchmarks for a sample project are shown in Table 1. Consider energy resources, on-site energy sources, and use of renewable energy, credits, utility rebates, or carbon offsets to mitigate environmental impacts of energy use.

Address a building's energy requirements in the following sequence:

1. **Minimize the impact of the building's functional requirements** by analyzing how the building relates to its external environment. Advocate changes in building form, aspect ratio, and other attributes that reduce, redistribute, or delay (shift) loads. The load calculation should be interactive so that the effect of those factors can be seen immediately.

2. **Minimize loads** by analyzing external and internal loads imposed on the building's energy-using subsystems, both for peak- and part-load conditions. Design for efficient and effective operation off-peak, where the majority of operating hours and energy use typically occurs.
3. **Maximize subsystem efficiency** by analyzing the diversified energy and power requirements of each energy-using subsystem serving the building's functional requirements. Consider static and dynamic efficiencies of energy conversion and energy transport subsystems, and consider opportunities to reclaim, redistribute, and store energy for later use.
4. **Study alternative ways to integrate subsystems** into the building by considering both power and time components of energy use. Identify, evaluate, and design each of these components to control overall design energy consumption. Consider the following when integrating major building subsystems:
   - Address more than one problem at a time when developing design solutions, and make maximum use of the building's advantageous features (e.g., windows, structural mass).
   - Examine design solutions that consider time (i.e., when energy use occurs), because sufficient energy may already be present from the environment (e.g., solar heat, night cooling) or from internal equipment (e.g., lights, computers) but available at times different from when needed. Active (e.g., heat pumps with water tanks) and passive (e.g., building mass) storage techniques may need to be considered.
   - Examine design solutions that consider the anticipated use of space. For example, in large but relatively unoccupied spaces, consider task or zone lighting. Consider transporting excess energy (light and heat) from locations of production and availability to locations of need instead of purchasing additional energy.
   - Never reject waste energy at temperatures usable for space conditioning or other practical purposes without calculating the economic benefit of energy recovery or treatment for reuse.
   - Consider or advocate design solutions that provide more comfortable surface temperatures or increase the availability of controlled daylight in buildings where human occupancy is a primary function.
   - Use easily understood design solutions, because they have a greater probability of use by building operators and occupants.
   - Where the functional requirements of a building are likely to change over time, design the installed environmental system to adapt to meet anticipated changes and to provide flexibility in meeting future changes in use, occupancy, or other functions.
   - Develop energy performance benchmarks, metrics, and targets that allow building owners and operators to better achieve the design intent. The effectiveness of these benchmarks was studied in ASHRAE research project 1627, which examines performance of K-12 schools and small office buildings that use the AEDGs (Jones et al. 2016).
   - Differentiate between peak loads for system design and selection and lower operating loads that determine actual energy use.

Building Energy Use Elements

Envelope. Control thermal conductivity by using insulation (including movable insulation), thermal mass, and/or phase-change thermal storage at levels that minimize net heating and cooling loads on a time-integrated (annual) basis.

- Minimize unintentional or uncontrolled thermal bridges, and include them in energy-related calculations because they can radically alter building envelope conductivity. Examples include wall studs, balconies, ledges, and extensions of building slabs.
- Minimize infiltration so that it approaches zero. (An exception is when infiltration provides the sole means of ventilation, such as in small residential units.) This minimizes fan energy consumption in pressurized buildings during occupied periods and minimizes heat loss (or unwanted heat gain, in warm climates) during unoccupied periods. In warm, humid climates, a tight envelope also improves indoor air quality. Reduce infiltration through design details that enhance the fit and integrity of building envelope joints in ways that may be readily achieved during construction (e.g., caulking, weatherstripping, vestibule doors, revolving doors), with construction meeting accepted specifications. Building envelope commissioning or testing can help verify these design and construction targets.
- Consider operable windows to allow occupant-controlled ventilation. This requires careful design of the building's mechanical system to minimize unnecessary HVAC energy consumption, and building operators and occupants should be cautioned about improper use of operable windows. CIBSE (2005) provides comprehensive design considerations for natural ventilation.

- Strive to maintain occupant radiant comfort regardless of whether the building envelope is designed to be a static or dynamic membrane. Design opaque surfaces so that average inside surface temperatures remain within 3 K of room temperature in the coldest anticipated weather (i.e., winter design conditions) and so that the coldest inside surface remains within 14 K of room temperature (but always above the indoor dew point). In a building with time-varying internal heat generation, consider thermal mass for controlling radiant comfort. In the perimeter zone, thermal mass is more effective when it is positioned inside the envelope's insulation.
- Effective control of solar radiation is critical to energy-efficient design because of the high level of internal heat production in most commercial buildings. In some climates, lighting energy consumption savings from daylighting techniques can be greater than the heating and cooling energy penalties that result from additional glazed surface area required, if the building envelope is properly designed for daylighting and lighting controls are installed and used. (In other climates, there may not be net savings.) Daylighting designs are most effective if direct solar beam radiation is not allowed to cause glare in building spaces.
- Design transparent parts of the building envelope to prevent solar radiant gain above that necessary for effective daylighting and solar heating. On south-facing facades (in the northern hemisphere), using low shading coefficients is generally not as effective as external physical shading devices in achieving this balance. Consider low-emissivity, high-visible-transmittance glazings for effective control of radiant heat gains and losses. For shading control, judicious use of vegetation may block excess gain year-round or seasonally, depending on the plant species chosen.

Lighting. Lighting is both a major energy end use in commercial buildings (especially office buildings) and a major contributor to internal loads by increasing cooling loads and decreasing heating loads. Design should both meet the lighting functional criteria of the space and minimize energy use. IES (2011) recommends illuminance levels for visual tasks and surrounding lighted areas. Principles of energy-conserving design within that context include the following:

- Energy use is determined by the lighting load (demand power) and its duration of use (time). Minimize actual demand load rather than just apparent connected load. Control the load rather than just area switching, if switching may adversely affect the quality of the luminous environment.
- Consider daylighting with proper controls to reduce costs of electric lighting. Design should be sensitive to window glare, sudden changes in luminances, and general user acceptance of daylighting controls. Carefully select window treatment (blinds, drapes, and shades) and glazing to control direct solar penetration and luminance extremes while maintaining the view and daylight penetration.
- Design the lighting system so that illumination required for tasks is primarily limited to the location of the task and comes from a direction that minimizes direct glare and veiling reflections on the task. When the design is based on nonuniform illuminance, walls should be a light to medium color or illuminated to provide visual comfort. In densely occupied work spaces, uniform distribution of general lighting may be most appropriate. Where necessary, provide supplementary task illumination. General ambient illumination should not be lower than a third of the luminance required for the task, to help maintain visually comfortable luminance ratios.
- Use local task lighting to accommodate needs for higher lighting levels because of task visual difficulty, glare, intermittently changing requirements, or individual visual differences (poor or aging eyesight).
- Group similar activities so that high illuminance or special lighting for particular tasks can be localized in certain rooms or areas, and so that less-efficient fixtures required for critical glare control do not have to be installed uniformly when they are only required sparsely.
- Use lighting controls throughout so lighting is available when and where it is needed, but not wasted when tasks are less critical or spaces are not fully occupied. Also consider user acceptance of control strategies to maximize energy saving.
- Only use lower-efficiency incandescent lamps in applications where their characteristics cannot be duplicated by other sources, because manufacturing of most incandescent lamps will be discontinued during the life of the building.
- Carry lighting design through the rest of the building's interior design. Reduced light absorption may be achieved by using lighter finishes, particularly on ceilings, walls, and partitions.

Other Loads.

- Minimize thermal impact of equipment and appliances on HVAC systems by using hoods, radiation shields, or other confining techniques, and by using controls to turn off equipment when not needed. Where practical, locate major heat-generating equipment where it can balance other heat losses. Computer centers or kitchen areas usually have separate, dedicated HVAC equipment. In addition, consider heat recovery for this equipment.
- Use storage techniques to level or distribute loads that vary on a time or spatial basis to allow operation of a device at maximum (often full-load) efficiency.

HVAC System Design.

- Consider separate HVAC systems to serve areas expected to operate on widely differing operating schedules or design conditions. For instance, systems serving office areas should generally be separate from those serving retail areas.
- Arrange systems so that spaces with relatively constant, weather-independent loads are served by systems separate from those serving perimeter spaces. Areas with special temperature or humidity requirements (e.g., computer rooms) should be served by systems separate from those serving areas that require comfort heating and cooling only. Alternatively, provide these areas with supplementary or auxiliary systems.
- Sequence the supply of zone cooling and heating to prevent simultaneous operation of heating and cooling systems for the same space, to the extent possible. Where this is not possible because of ventilation, humidity control, or air circulation requirements, reduce air quantities as much as possible before incorporating reheating, recooling, or mixing hot and cold airstreams. For example, if reheat is needed to dehumidify and prevent overcooling, *only* ventilation air needs to be treated, not the entire recirculated air quantity. Finally, reset supply air temperature up to the extent possible to reduce reheating, recooling, or mixing losses.
- Provide controls to allow operation in occupied and unoccupied modes. In occupied mode, controls may provide for a gradually changing control point as system demands change from cooling to heating. In unoccupied mode, ventilation and exhaust systems should be shut off if possible, and comfort heating and cooling systems should be shut off except to maintain space conditions ready for the next occupancy cycle.
- In geographical areas where diurnal temperature swings and humidity levels permit, consider judicious coupling of air distribution and building structural mass to allow nighttime cooling to reduce the requirement for daytime mechanical cooling.
- High ventilation rates, where required for special applications, can impose enormous heating and cooling loads on HVAC equipment. In these cases, consider recirculating filtered and cleaned

Licensed for single user. © 2021 ASHRAE, Inc.

air to the extent possible, rather than 100% outdoor air. Also, consider preheating outdoor air with reclaimed heat from other sources.

HVAC Equipment Selection.

- To allow HVAC equipment operation at the highest efficiencies, match conversion devices to load increments, and sequence the operation of modules. Oversized or large-scale systems should never serve small seasonal loads (e.g., a large heating boiler serving a summer-service water-heated load). Include specific low-load units and auxiliaries where prolonged use at minimal capacities is expected.
- Select the most efficient (or highest-COP) equipment practical at both design and reduced capacity (part-load) operating conditions.
- When selecting large-power devices such as chillers (including their auxiliary energy burdens), perform an economic analysis of the complete life-cycle costs. See Chapter 37 of the 2019 *ASHRAE Handbook—HVAC Applications* for more information on detailed economic analysis.
- Keep fluid temperatures for heating equipment devices as low as practical and for cooling equipment as high as practical, while still meeting loads and minimizing flow quantities.

Energy Transport Systems. Energy should be transported as efficiently as possible. The following options are listed in order of theoretical efficiency, from the lowest energy transport burden (most efficient) to the highest (least efficient):

1. Electric wire or fuel pipe
2. Two-phase fluid pipe (steam or refrigerant)
3. Single-phase liquid/fluid pipe (water, glycol, etc.)
4. Air duct

Select a distribution system that complements other parameters such as control strategies, storage capabilities, conversion efficiency, and utilization efficiency.

The following specific design techniques may be applied to thermal energy transport systems:

Steam Systems.

- Include provisions for seasonal or nonuse shutdown.
- Minimize venting of steam and ingestion of air, with design directed toward full-vapor performance.
- Avoid subcooling, if practical.
- Return condensate to boilers or source devices at the highest possible temperature.

Hydronic Systems.

- Minimize flow quantity by designing for the maximum practical temperature range.
- Vary flow quantity with load where possible.
- Design for the lowest practical pressure rise (or drop).
- Provide *operating* and *idle* control modes.
- When locating equipment, identify the critical pressure path and size runs for the minimum reasonable pressure drop.

Air Systems.

- Minimize airflow by careful load analysis and an effective distribution system. If the application allows, supply air quantity should vary with sensible load (i.e., VAV systems). Hold the fan pressure requirement to the lowest practical value and avoid using fan pressure as a source for control power.
- Provide *normal* and *idle* control modes for fan and psychrometric systems.
- Keep duct runs as short as possible, and keep runs on the critical pressure path sized for minimum practical pressure drop.

Power Distribution.

- Size transformers and generating units as closely as possible to the actual anticipated load (i.e., avoid oversizing to minimize fixed thermal losses).
- Consider distribution of electric power at the highest practical voltage and load selection at the maximum power factor consistent with safety.
- Consider tenant submetering in commercial and multifamily buildings as a cost-effective energy conservation measure. (A large portion of energy use in tenant facilities occurs simply because there is no economic incentive to conserve.)

Domestic Hot-Water Systems.

- Choose shower heads that provide and maintain user comfort and energy savings. They should not have removable flow-restricting inserts to meet flow limitation requirements.
- Consider point-of-use water heaters where their use will reduce energy consumption and annual energy cost.
- Consider using storage to facilitate heat recovery when the heat to be recovered is out of phase with the demand for hot water or when energy use for water heating can be shifted to take advantage of off-peak rates.

Controls. Well-designed digital control provides information to managers and operators as well as to the data processor that serves as the intelligent controller. Include the energy-saving concepts discussed previously throughout the operating sequences and control logic. However, energy conservation should not be sought at the expense of adequate performance; in a well-designed system, these two parameters are compatible. See Chapter 7 of this volume and Chapter 47 of the 2019 *ASHRAE Handbook—HVAC Applications* for more information on controls.

CHAPTER 36

CLIMATE CHANGE

Overview of Climate Science 36.1
Mitigating Climate Change 36.11
Adapting to Climate Change 36.16
Conclusion 36.20
Glossary 36.20

The ASHRAE Position Document on Climate Change states unequivocally that climate change "… is the most formidable environmental challenge ever faced by society" (ASHRAE 2018b).Historically, designers and planners assumed a stable climate, and heating and cooling system designs were based on statistics calculated from past weather data, typically for a recent 30-year period. However, we are now experiencing major changes in climate both globally and locally, at rates 10 times greater than seen since the end of the last ice age 20,000 years ago – over decades instead of centuries or millennia (National Academy of Sciences and The Royal Society 2020). This presents a challenge for designers of buildings and their systems, as well as for building operators, since buildings are expected to operate robustly for decades. This chapter stresses the importance of cultivating climate change literacy among designers and operators of buildings and their systems.

This chapter lays out how practicing engineers and architects can use their best professional judgment to mitigate the environmental impact of the buildings and systems they design and adapt them to a changing climate. This content builds upon and complements existing ASHRAE guidance on minimizing the environmental impact of buildings and their systems. For example, ASHRAE publishes whole-building energy and water efficiency standards like Standard 90.1 – Energy Standard for Buildings Except Low-Rise Residential Buildings, as well as guidance on reducing the Greenhouse Gas (GHG) emissions of HVAC&R systems through improved efficiency and phasing out refrigerants with high Global Warming Potential (GWP) and ozone-depleting potential. Other related work concerns the impacts of flooding and other extreme weather events on the ability of buildings to preserve human life and maintain acceptable Indoor Environmental Quality (IEQ). A core theme of this chapter, therefore, is that while there are trade-offs between mitigation and adaptation, both are required.

While there are currently no standardized methods endorsed by ASHRAE to integrate changing climatic information into building and HVAC&R system design, this does not preclude action by practicing engineers and architects. Repeatable and defensible methods can inform and enhance existing ASHRAE standards and guidelines, like those of other professional organizations such as Chartered Institution of Building Services Engineers (CIBSE), American Society of Civil Engineer (ASCE), American Society of Mechanical Engineers (ASME), and American Association of State Highway and Transportation Officials (AASHTO). Resources for assessing the impact of a changing climate on building and system performance exist, both within and outside ASHRAE, and are discussed in this chapter. It is important to recognize that, while climate change will have impacts of varying severity and duration around the world, many designers and operators may find that the buildings and systems they are designing or refurbishing currently will end up in a different climate during their operational life.

This chapter does not lay out prescriptive guidelines to account for changing conditions during the service life of an asset, i.e., a building or its equipment and systems. Instead, practitioners must be informed by their own risk tolerance and risk appetite, a realistic assessment of their climate literacy, their ability to assess the implications of the latest available information on design, and their skills to manage and communicate realistic performance expectations to their clients (WFEO 2015). In this context, the evolution of the standard of care within practice, the use of judgment, and consideration of professional liability compels professionals to carefully consider their professional consultative role as only proposing actions might not meet professional obligations to protect health, safety and welfare (WFEO 2015; Marjanac, Patton, and Thornton 2017; Engineers Canada 2018; Moran and Mihaly 2018).

This chapter borrows terms from the mathematics of risk and uncertainty analysis, using the likelihood terminology outlined in Table 1, as determined by US National Climate Assessment and the Intergovernmental Panel on Climate Change (IPCC). (As an example, a 66-100% probability in Table 1 for Likely can be interpreted as a likelihood of more than 2 out of 3 chances for this certainty, while Very Likely means more than 9 times out of 10 chances.) This should not be taken to mean that the authors are not sure if the climate is changing. Rather, only the magnitude and timing of the changes are not known with certainty and precision. For example, it is impossible to predict the exact change in return periods of heat waves of a particular severity – only that recent shifts in the distribution of temperatures at a location indicate that the probabilities will be different from the past. Not only have heat waves not been predicted well so far, they are unlikely to be predictable because of the complexity of climatic interactions and scales involved (Horton et al. 2016). Even so, it is well established that shifts in temperature distributions significantly change heat have frequencies. This lack of precise predictions is not a reason to delay or refrain from action, as much as not knowing the exact date and time of a fire is not a reason to not install a fire-suppression system.

The content is divided into three sections: Overview of Climate Science, Mitigating Climate Change and Adapting to Climate Change. The first section summarizes the latest available scientific information relevant to the design and operation of buildings and their systems. The second summarizes strategies for mitigation. The third section provides designers with guidance on adaptation, i.e., creating agile designs for resilient buildings.

1. OVERVIEW OF CLIMATE SCIENCE

This short discussion of the science of climate change and what it means to human society is primarily based on the findings of the two volumes of the 4th U.S. National Climate Assessment (NCA4) (USGCRP 2017). These reports are, in turn, consistent with other climate assessment findings, such as those of the IPPC Fifth Assessment Report (AR5) (IPCC 2014b). The NCA4 fulfils the mandate of the Global Change Research Act of 1990 that the U.S. Global Change Research Program (USGCRP) deliver a report to United States Congress and the President no less than every four years that

"1) integrates, evaluates, and interprets the findings of the Program…; 2) analyzes the effects of global change on the natural environment, agriculture, energy production and use, land and water resources, transportation, human health and welfare, human social systems, and biological diversity; and 3) analyzes current

Table 1 System of Likelihood Terms Corresponding to Probabilities from Fourth National Climate Assessment (NCA4) and IPCC's Fifth Assessment Report (AR5) (IPCC 2014b; USGCRP 2017)

Virtually certain	Very Likely	Likely	About as likely as not	Unlikely	Very Unlikely	Exceptionally Unlikely
99-100%	90-100%	66-100%	33-66%	0-33%	0-10%	0-1%

trends in global change, both human-induced and natural, and projects major trends for the subsequent 25 to 100 years" ("Global Change Research Act of 1990" 1990).

The findings in NCA4 are based on a large body of scientific, peer-reviewed research, as well as several other publicly available sources, including well-established and carefully-evaluated observational and modeling datasets. The findings of the peer-reviewed published research and these assessments are that applying the basic principles of conservation of energy and thermal radiation governed by Planck's law, it is virtually certain that the observed increase in Greenhouse Gases (GHG) concentrations has had, and is having, a global warming effect, with resulting implications on severe weather, sea level rise, and other aspects of the Earth's climate system.

The most recent models presented in the aforementioned publications projected global climate along several different paths, called Representative Concentration Pathways (RCP). Each RCP has a different radiative forcing by 2100 that corresponds to different emissions and GHG concentrations throughout the century and beyond (IPCC 2014b). Recent evidence has shown that global emissions have generally been tracking close to the highest emission scenario – RCP 8.5. Even so, the first half of 2020 showed slightly lower tracking and the effects of the disruption on emissions due to the COVID-19 pandemic and this is expected to reduce the annual emissions temporarily by 6% (IEA 2020).

The IPCC 6th Assessment Report (AR6) is still in progress and is expected to have completed portions in 2021. A similar update for NCA5 is expected later.

Climate vs Weather

It is important to formally distinguish between weather and climate. The words 'weather' and 'climate' are not interchangeable, though they are often confused outside specialist circles. Weather is what a location experiences on a given day in a year. Climate is the collection of statistical properties, e.g., mean, variance, probabilities of extreme events, of recorded weather data for a 30-year period for that location and that time of year. Climate change is the deviation from these historical statistics for that location and time of year. Weather refers to atmospheric conditions that occur locally over short periods of time – from minutes to hours or days. Familiar examples include rain, snow, clouds, winds, floods or thunderstorms. Climate, on the other hand, refers to the long-term statistics and patterns of temperature, humidity, rainfall, etc. over seasons, years and decades.

Global Signatures of Climate Change

Temperatures are increasing in the atmosphere (troposphere), on land, and in the oceans. Global decadal averaged temperature (as calculated from instrumental records over both land and oceans) has increased by about 1.9°F (1.1°C) since the lowest ten-year average temperature in the decade of 1900-1909 (Figure 1). This change is by far the largest increase in the globally averaged temperature over at least the last 1,700 years and probably much longer. Additionally, this increase is occurring at a much faster rate than the climate tends to change historically. The most recent six years are the six warmest in the instrumental record (2014 [6th], 2015 [3rd], 2016 [1st], 2017 [4th], 2018 [5th], 2019 [2nd]) (Zhang et al. 2019).

However, recorded temperature changes are not the only indication of a warming climate: other observations are also consistent

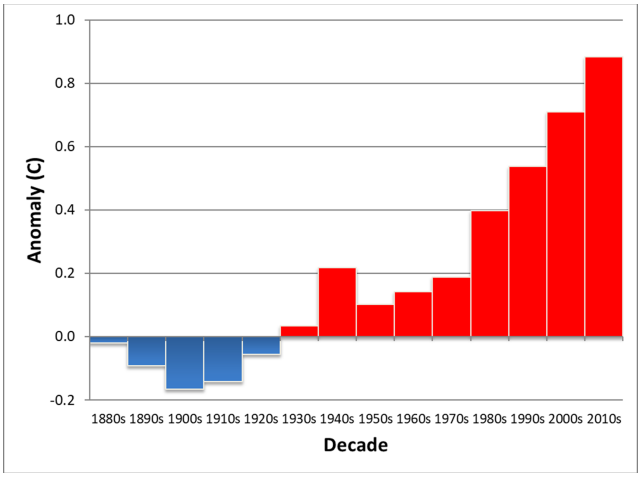

Fig. 1 Globally averaged surface temperature anomalies by decade from 1880-1889 ("1880s") to 2010-2019 ("2010s") (Zhang et al. 2019). Reference period is 1901-1960.

with a global average increase in temperature. Temperatures in the lower atmosphere and ocean have increased, as have near-surface humidity and global mean sea level. In addition, the ocean heat content has increased dramatically because more than 90% of the energy gained in the combined ocean–atmosphere system over recent decades has gone into the ocean. There are many other signatures of the changing climate. For example, atmospheric humidity is generally increasing globally, which is an expected response of a warming climate. Arctic sea ice has declined since at least 1979, with accelerating ice loss since 2000. With only a few exceptions, glaciers are declining around the world. The Greenland ice sheet mass has been declining at an accelerating rate (USGCRP 2017; 2018). See the section on Changes in the Climate System Related to Recent Global Warming for more information.

Natural and Human Drivers of Climate Change

The energy balance at Earth's surface is controlled by several factors: incoming solar radiation, solar radiation absorbed and reflected by the atmosphere, infrared radiation emitted by Earth, and infrared radiation absorbed and re-emitted by the atmosphere, primarily by greenhouse gases, as shown in Fig. 2 (IPCC 2013). Changes in these factors affect Earth's radiative balance and therefore its climate, including temperature, precipitation, and other variables through a complex set of physical processes. These changes, in turn, trigger feedback processes, many of which tend to amplify the resulting changes in climate.

Nearly a third (29.4%) of incoming shortwave energy from the sun is reflected back to space, and the remainder is absorbed by the Earth system (Figure 2). The fraction of sunlight scattered back to space is determined by the reflectivity (albedo) of clouds, land surfaces (including snow and ice), oceans, and particles (aerosols) in the atmosphere. The cloud cover, snow cover, and ice cover are particularly strong determinants of the amount of sunlight reflected back to space because their albedos are much higher than those of land and oceans. Decreases in the total area covered by snow and ice

Licensed for single user. © 2021 ASHRAE, Inc.

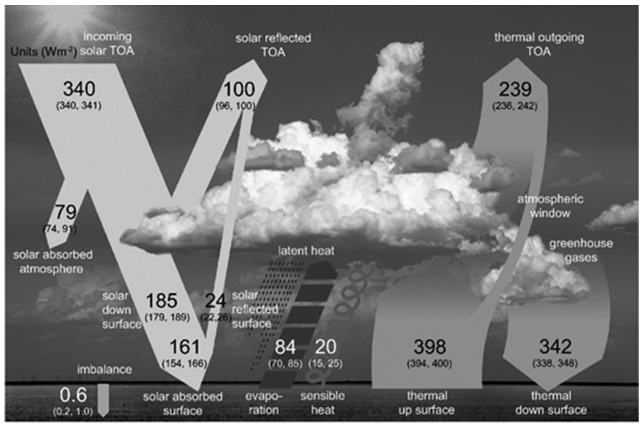

Fig. 2 Global mean energy budget of Earth under present-day climate conditions. Numbers state magnitudes of the individual energy fluxes in watts per square meter (W/m2) averaged over Earth's surface, adjusted within their uncertainty ranges to balance the energy budgets of the atmosphere and the surface. Numbers in parentheses attached to the energy fluxes cover the range of values in line with observational constraints. Fluxes shown include those resulting from feedbacks. Top of Atmosphere (TOA) reflected solar values given here are based on observations 2001–2010; TOA outgoing longwave is based on 2005–2010 observations. (Figure 2-11, IPCC 2013).

increases the absorption of solar energy by exposing darker soil or ocean surfaces.

In addition to reflected sunlight, Earth loses energy through the emission of infrared (longwave) radiation from its surface and atmosphere. GHGs in the atmosphere absorb most of this radiation, leading to a warming of the surface and atmosphere. The principal GHGs are water vapor (H2O), carbon dioxide (CO2), methane (CH4), nitrous oxide (N2O) and ozone (O3). All of these gases have major natural sources, but the atmospheric concentrations of all of them, except H2O, are being greatly and directly affected by human activities (AR5, IPCC 2014). Water is rapidly exchanged between the land, ocean, and atmosphere, and is itself an important part of Earth's climate system. In fact, the naturally occurring GHGs with the largest concentrations in Earth's atmosphere – principally H2O and CO2 – keep the near-surface air temperature about 60°F (33°C) warmer than it would be in their absence, assuming albedo is held constant.

While it has long been recognized that the Earth's climate can change because of natural influences, over the last century it has become increasingly clear that human-related forcings (i.e., drivers for changing the energy balance in the Earth system that lead to climate change) can also have, and are having, a large impact upon the climate system. Though climate drivers of significance over the industrial era include both types of forcings, the most significant factor in the large changes in climate over the last century has been the increasing concentrations in GHGs, especially CO2, CH4, and N2O. That is, it is very likely that more than half of the observed warming is from anthropogenic forces (Bindoff et al. 2013).

Causes of Observed Global Warming

Natural causes of climate change do not explain the rapid warming observed in recent decades. Changes in solar irradiance directly impact the climate system (and were an important factor in many previous changes in climate) because it is Earth's primary energy source. However, satellite observations (available since 1979) indicate that the energy from the sun has changed little over at least the past 40 years, and thus is not responsible for the observed warming.

Explosive volcanic eruptions can inject substantial amounts of sulfur dioxide (SO2) and ash into the stratosphere, which can lead to significant short-term cooling effects (1-3 years). The oceans can also respond to the cooling effect, and changes in ocean circulation patterns can last for decades after major eruptions. Additionally, internal variability in Earth's climate system, such as the El Niño Southern Oscillation (ENSO), causes limited annual- to decadal-scale variations in regional temperatures and other climate parameters that do not contribute to long-term trends. El Niño events are characterized by a warming of the surface waters in the eastern equatorial Pacific and result in increases in temperature. La Niña events have the opposite effect. These events typically last 1-3 years and their primary effect on temperature is transitory. There has not been an increase in El Niño events relative to La Niña events. Other internal variations in the climate system can last for decades, but there is no evidence that any such variation has caused the observed warming.

According to the Fourth U.S. National Climate Assessment (USGCRP 2017), natural variability is only a minor factor in the observed changes in climate over the last century. It is likely (> 66% probability) that natural variability has contributed between -0.18°F (-0.1°C) and 0.18°F (0.1°C) to changes in surface temperatures from 1951 to 2010 (Bindoff et al. 2013). Similarly, natural emissions and sinks of GHGs and tropospheric aerosols have varied over the industrial era but have not contributed significantly to the observed changes in climate. Such climate forcing effects from gases and particles can also be translated into an equivalent radiative forcing.

Other potential natural drivers of climate change have also been well studied (such as the effects of cosmic rays on cloud formation), but global radiative effects from those drivers are not likely to be a significant contributor to the observed climate trends. There are other known drivers of natural origin that operate on much longer timescales. For example, changes in Earth's orbit (Milankovitch cycles) that lead to the ice ages have occurred about every 100,000 years during the last two million years and should currently have Earth in a cooling phase. Also, changes in atmospheric carbon dioxide (CO2) can be affected via chemical weathering of rock on time scales of a century or longer and could have contributed to past changes in climate.

Several human-related activities also cause changes in climate. Major changes in land use and land cover have occurred in some areas. Some urban areas have expanded. In general, urbanization contributes to warming through the replacement of natural land cover with impervious surfaces that have higher heat capacities and limited or no vegetation to provide evaporative cooling. Investigations of the impact of increased urbanization show a small but detectable contribution to warming. Deforestation and reforestation have occurred in various parts of the globe. The effects of these changes in land cover are of varying magnitude: while the effect on total carbon dioxide concentration is substantial, the change in global average surface temperature is relatively small because the percentage of the globe covered by forests is relatively small.

The most important human-caused change is the altered composition of the atmosphere, specifically increases in certain greenhouse gases. Carbon dioxide, in particular, has increased in concentration from about 280 ppm at the beginning of the Industrial Revolution to about 410 ppm today. This increase has been caused primarily by the burning of fossil fuels, but land-use change – including deforestation – has made a substantial contribution as well. Concentrations of other important GHGs – including methane, nitrous oxides, and several chlorofluorocarbons – have also increased as a result of human activity. Numerous experiments, using both simplified and highly complex climate models, strongly

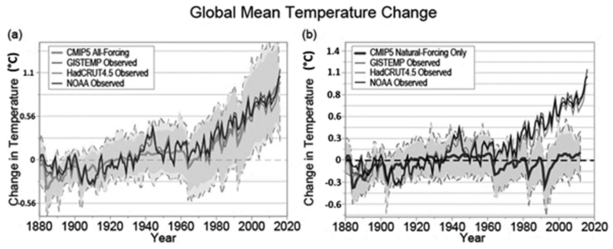

Fig. 3 Comparison of observed global mean temperature anomalies from three observational datasets to the fifth Coupled Model Intercomparison Project (CMIP5) climate model historical experiments using: (a) anthropogenic and natural forcings combined, or (b) natural forcings only (Knutson et al. 2017).

suggest that the GHG warming effect is large enough to account for the observed increase in global average temperature. Furthermore, no other single or combined potential warming factors can account for this increase (Figure 3).

Particles (also referred to as aerosols) play a profound and complex role in the Earth's climate through radiative effects in the atmosphere and on snow and ice surfaces and through effects on cloud formation and properties. Human activities have made important changes in the concentrations of some of the key types of particles, especially from the burning of fossil fuels. Particle types are categorized by composition, e.g., sulfate, black carbon, organic, nitrate, dust, and sea salt. Black carbon particles (also called soot) tends to have a warming effect, while many other particles, like sulfates, reflect sunlight and have a cooling effect.

Particles have a lifetime of days to weeks in the troposphere. The combined forcing of aerosol–radiation and aerosol–cloud interactions is negative (cooling) over the industrial era (high confidence), offsetting part of the increasing greenhouse gas forcing. The magnitude of this offset, globally averaged, has declined in recent decades, despite increasing trends in aerosol emissions or abundances in some regions of the world (especially in China and India).

The bottom line is that the best explanation supported by observed data is that the increase in global temperature is largely or wholly caused by human-induced increases in greenhouse gas concentrations, the most important of which is the increase in atmospheric CO2 from fossil fuel combustion. Fossil fuel emissions can be distinguished from naturally-occurring CO2 because of the differing isotopic distributions. Decreases in the ratio of atmospheric carbon-13 and carbon-14 to carbon-12 confirm that fossil fuel combustion is largely the source of the increased CO2. Deforestation and other land use change, cement manufacturing, as well as other heavy GHG producing industries, also contribute to the increase in CO2 concentrations (Figure 4).

Climate Change in the Distant Past

Paleoclimate records are proxy data sources that extend the climate record hundreds-to-millions of years into the past from the mid-19th century backwards to substitute for the instrumental observations that did not exist then. These records demonstrate that there have been long-term natural changes in the climate. Before the emissions of greenhouse gases from fossil fuels and other human-related activities became a major factor over the last few centuries, the strongest drivers of climate change during the last few thousand years had been volcanoes and land-use change (which has both albedo and greenhouse gas emissions effects). Based on a number of proxies for temperature (for example, from tree rings, fossil pollen, corals, ocean and lake sediments, and ice cores), temperature records are available for the last 2,000 years on hemispherical and continental scales. High-resolution temperature records for North America extend back less than half of this period. For this era, there is a general long-term cooling trend until the rapid increase in temperature over the last 150–200 years. For context, global annual averaged temperatures for 1986–2015 are likely much higher than any similar period over the past 2,000 years or longer and appear to have risen at a more rapid rate during the last 3 decades.

Global temperatures of the magnitude observed recently (and projected for the rest of this century) are related to very different forcings than past climates, and studies of past climates suggest that such global temperatures were likely last observed during the Eemian period (the last interglacial epoch), 125,000 years ago. At that time, global temperatures were, at their peak, about 1.8°F–3.6°F (1°C–2°C) warmer than preindustrial temperatures. Coincident with these higher temperatures, sea levels during that period were about 16–30 feet (6–9 meters) higher than modern levels.

Recent studies suggest that the Eemian period warming can be explained in part by the changes in incoming solar radiation as a result of cyclic changes in the shape of Earth's orbit around the sun (Milankovitch Cycle), even though greenhouse gas concentrations were similar to preindustrial levels. Equilibrium climate with current levels of greenhouse gas concentrations (about 410 ppm CO2) most recently occurred about 3 million years ago during the Pliocene. With such high CO2 levels existing for a long time period (centuries), global temperatures were as much as 5.4°F–7.2°F (3°C–4°C) higher than today, and sea levels were about 82 feet (25 meters) higher.

Feedbacks in the Climate Systems

Climate feedbacks are processes that can either amplify or diminish the effects of climate forcings. A feedback that increases an initial warming is called a positive feedback, and onme that reduces an initial warming is a negative feedback.

Planck Feedback. When the temperatures of Earth's surface and atmosphere respond to a positive radiative forcing, more infrared radiation is emitted into the lower atmosphere. In other words, when the surface and atmospheric temperatures increase, so does the amount of longwave radiation emitted back to space. This process, known as the Planck feedback, serves to restore radiative balance at the tropopause. It is a negative feedback, and the strongest and primary stabilizing feedback in the climate system. Other feedbacks largely tend to increase the overall forcing and resulting temperature change.

Water Vapor Feedback. Warmer air can contain more moisture (water vapor) than cooler air – about 3.5% more per °F (7% more per °C). Thus, as global temperatures increase, the total amount of water vapor in the atmosphere also increases, adding further to greenhouse warming – a positive feedback. The water vapor feedback is responsible for more than doubling the direct climate warming from CO2 emissions alone. Observations confirm that global tropospheric water vapor has increased commensurate with measured warming.

Snow-albedo Feedback. Snow and ice are highly reflective to solar radiation relative to land surfaces and the ocean. Loss of snow cover, glaciers, ice sheets, or sea ice resulting from climate warming lowers Earth's surface albedo. The losses create the snow-albedo feedback because subsequent increases in absorbed solar radiation lead to further warming as well as changes in turbulent heat fluxes at the surface. For seasonal snow, glaciers, and sea ice, a positive albedo feedback occurs where light-absorbing aerosols are deposited to the surface, darkening the snow and ice and accelerating the loss of snow and ice mass. For ice sheets (for example, on Antarctica and Greenland), the positive radiative feedback is further amplified by dynamical feedbacks on ice-sheet mass loss. Specifically,

Licensed for single user. © 2021 ASHRAE, Inc.

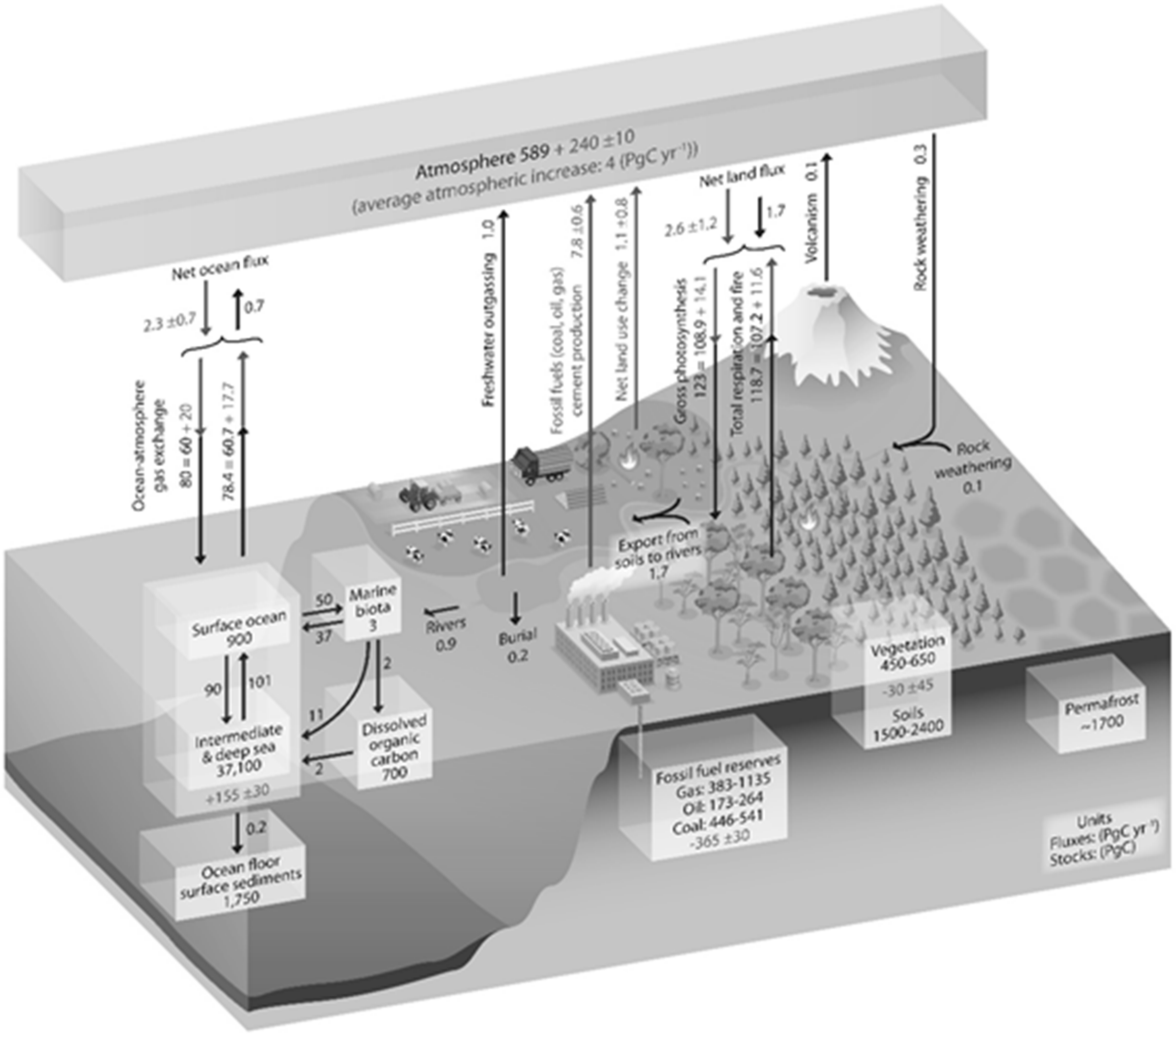

Fig. 4 Simplified diagram of the global carbon cycle. Numbers denote reservoir mass, also called " carbon stocks " in Pg C (1 Pg C = 1015 g C) and annual carbon exchange fluxes (in Pg C / yr) between the atmosphere and its two major sinks, the land and ocean. Black numbers and arrows indicate reservoir mass and exchange fluxes estimated for the time prior to the Industrial Era (1750). Grey arrows and numbers indicate annual " anthropogenic " fluxes averaged over the 2000–2009 time period. These fluxes are a perturbation of the carbon cycle during Industrial Era post 1750. The atmospheric inventories have been calculated using a conversion factor of 2.12 PgC per ppm. (Figure 6.1, Ciais et al. 2013)

since continental ice shelves limit the discharge rates of ice sheets into the ocean; any melting of the ice shelves accelerates the discharge rate, creating a positive feedback on the ice-stream flow rate and total mass loss.

Cloud Feedbacks. An increase in cloudiness has two direct impacts on radiative fluxes. First, it increases scattering of sunlight, which increases Earth's albedo and cools the surface (the shortwave cloud radiative effect). Second, it increases trapping of infrared radiation, which warms the surface (the longwave cloud radiative effect). A decrease in cloudiness has the opposite effects. Clouds have a relatively larger shortwave effect when they form over dark surfaces (such as oceans) than over higher albedo surfaces (such as sea ice and deserts). Analyses show that the net radiative effect of cloud feedbacks has been positive over the industrial era. The net cloud feedback can be broken into components, where the longwave cloud feedback is positive and the shortwave feedback is near-zero, though the two do not add linearly. Uncertainty in cloud feedback remains the largest source of inter-model differences in calculated climate sensitivity.

There are other relevant minor feedbacks. For example, climate change alters the atmospheric abundance and distribution of some radiatively active species (atmospheric gases) by changing natural emissions, atmospheric photochemical reaction rates, atmospheric lifetimes, transport patterns, or deposition rates. These can affect the concentrations of GHGs. Also, climate-driven ecosystem changes that alter the carbon cycle potentially impact atmospheric CO2 and CH4 abundances.

Changes in Climate System Related to Recent Global Warming

Additional changes in the climate system are directly related to the increase in GHGs and the resulting global warming. Sea level is rising at an accelerating rate due to melting of glaciers and land-based ice sheets and to thermal expansion of sea water as oceans warm. Global Mean Sea Level (GMSL) has risen by about 7–8 inches (about 16–21 cm) since 1900, with about 3 of those inches (about 7 cm) occurring since 1993. Human-caused climate change has made a substantial contribution to GMSL rise since 1900, con-

Licensed for single user. © 2021 ASHRAE, Inc.

tributing to a rate of rise that is greater than during any preceding century in at least 2,800 years. Local sea level rise can be different than the global average due to to changes in the Earth's gravitational field and rotation from melting of land ice, changes in the ocean circulation, and vertical land motion.

Certain types of extreme weather conditions have changed and have been attributed to global warming. The frequency and intensity of extreme heat has increased, and extreme cold has become less intense in most areas of the globe. Extreme precipitation has become more frequent at most long-term reporting stations, likely the result of larger amounts of water vapor over the warming oceans.

Observations show that significant declines have occurred in Arctic sea ice extent and thickness, Northern Hemisphere snow cover, and the volume of mountain glaciers and continental ice sheets. Evidence suggests in many cases that the net loss of mass from the global cryosphere (the frozen water part of the Earth system) is accelerating. Arctic sea ice area, thickness, and volume have declined since at least 1979. Annually-averaged Arctic sea ice extent has decreased by 3.5% – 4.1% per decade since 1979, with much larger reductions in summer and fall. While current generation climate models project a nearly ice-free Arctic Ocean in late summer by mid-century, they still simulate weaker reductions in volume and extent than what has already been observed, suggesting that projected changes are underestimating future ice melt.

Satellite measurements indicate that mass loss from mountain glaciers around the world, the Greenland Ice Sheet, and the Antarctic Ice Sheet continues and is accelerating in some cases. The annually averaged ice mass from 37 global reference glaciers has decreased every year since 1984. Over the last decade, the Greenland Ice Sheet mass loss has accelerated, losing 244 ± 6 Gigaton per year (Gt/yr) on average between January 2003 and May 2013. Mass loss increased from 41 ± 17 (Gt/y) in 1990–2000, to 187 ± 17 Gt/y in 2000–2010, to 286 ± 20 Gt/y in 2010–2018 (Mouginot et al. 2019). Major ice loss has been seen in Antarctica as well, increasing from 40 ± 9 Gt/y in 1979–1990 to 50 ± 14 Gt/y in 1989–2000, 166 ± 18 Gt/y in 1999–2009, and 252 ± 26 Gt/y in 2009–2017 (Rignot et al. 2019). There is great concern about the possibility of significant ice loss from the West Antarctica ice sheet over this century. Observed rapid mass loss from West Antarctica is attributed to increased glacial discharge rates due to diminishing ice shelves from the surrounding ocean becoming warmer.

Observed Changes in Global Climate Conditions

Globally, nearly all land areas have warmed (Figure 5). The greatest warming has occurred in central Asia and eastern Brazil. A few areas have warmed by less than 1°F 0.56°C), including south Asia and the Middle East. The Arctic has been warming at about twice the rate of the rest of the world. While this global mean warming is not always a useful indicator of the metrics relevant to systems design or performance simulation, it is indicative of impacts on climatic conditions at individual stations.

Annual mean temperature has increased in the United States (U.S.), by about 1.8°F (1.0°C) since 1901, similar to the global increase in temperature. The increase in temperature has not been uniform. Larger increases have occurred in the western and northern U.S., while the Southeast has warmed by less than 1°F (0.56°C) (Figure 6). In a few locations in the southeastern U. S., there has been no net change in temperature since 1901. The Southeast is one of the few regions in the world that has experienced little overall warming of daily maximum temperatures since 1900. The reasons for this have been the subject of much research, and hypothesized causes include both human and natural influences. However, since the early 1960s, the Southeast has been warming at a similar rate as the rest of the U.S. Data from two stations is shown in the next section as an example, along with climate model projections. Since 1970, almost all areas of the U.S. have seen an increase in cooling

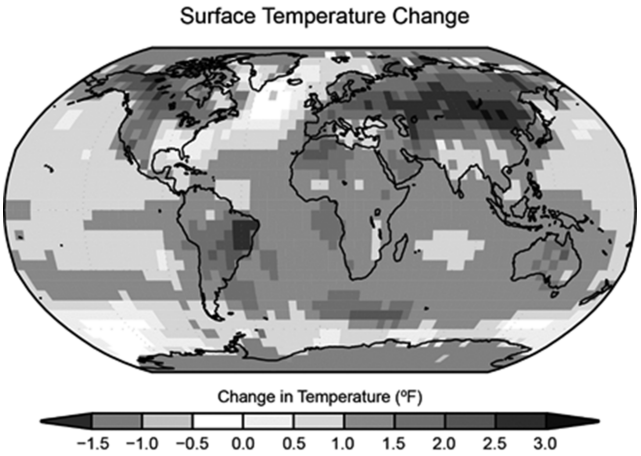

Fig. 5 Surface temperature change (in °F) for the period 1986–2015 relative to 1901–1960 from the NOAA National Centers for Environmental Information's (NCEI) surface temperature product (USGCRP 2017). Similar, interactive maps can be found at www.ncdc.noaa.gov/cag /global/mapping.

degree days (CDDs) and a decrease in heating degree days (HDDs). The largest percentage trends are in the northern U.S. for heating degree days and the southern U.S. for cooling degree days. On a national average basis, HDDs have decreased by about 14% since 1970 while CDDs have increased by about 21% (Kunkel 2019).

Station-level Trend Data

Records over long time periods exist only for a very small number of locations around the world. This makes identifying trends to verify climate model predictions difficult on a station-by-station basis, and this is especially harder with shorter records. For example, the most recent updates to Chapter 14 show statistically significant trends only in some locations, in large part because the short-term inter-annual variability in an individual station washes out the long-term trend.

An approximation of localized changes, expressed in terms of changes in climate zone classification over 30 years, is shown in Figure 6. The pole-ward creep of warmer climate zones is clearly visible. This map is drawn from time series of temperatures for a uniform grid over the earth output by a reanalysis model, MERRA-2 (Gelaro et al. 2017). A reanalysis model attempts to form a consistent three-dimensional picture of the atmosphere by reconciling a numerical weather model-based estimate with all available historical observations including satellites, weather balloons, aircraft, etc. Thus, we are able to use a reanalysis model to ascertain broad trends across the world using a consistent length of record. As is discussed in more detail in Chapter 14 (Climatic Design Information) of this volume, while the overall picture is clearly one of warming, the magnitudes of observed trends vary between stations.

While the overall picture is clearly warming, the currently-observed changes in design conditions for individual stations, when observed, do not suggest more oversizing of equipment. That is, the change in design conditions over the lifetime of HVAC equipment is not enough to justify further oversizing. However, the change in climate zones will continue and designers must consider this in design decisions. Refer to the sections below for more information on design considerations.

Numerous studies have found that heavy (unusually large) precipitation events have increased in both intensity and frequency in the U.S. (Figure 7). These studies have investigated a wide range of

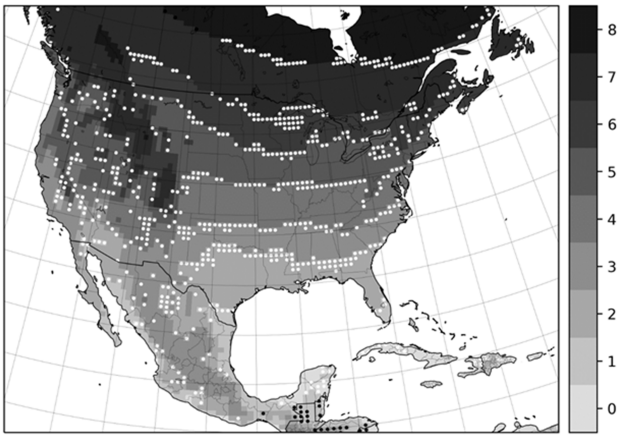

Fig. 6 ASHRAE climate zone changes between 1980-1999 and 2000-2019. Each shade of gray represents a 'current' thermal climate zone, i.e., using MERRA-2 outputs (Gelaro et al. 2017) from 2000-2019. A white dot represents an area that has moved to a warmer climate zone than it was in 1980-1999. This trend is most evident at the borders of climate zones, and easiest to see in central North America. A black dot represents a climate zone that has become colder in this period, a small number of which can be seen south of Mexico. Tellingly, these maps include ASHRAE climate zone 0 (over the Caribbean), which had to be added in the 2016 edition of the handbook to accommodate 'very hot' climates. Maps of other regions are available online at www.ashrae.org/technical-resources/bookstore/weather-data-center.

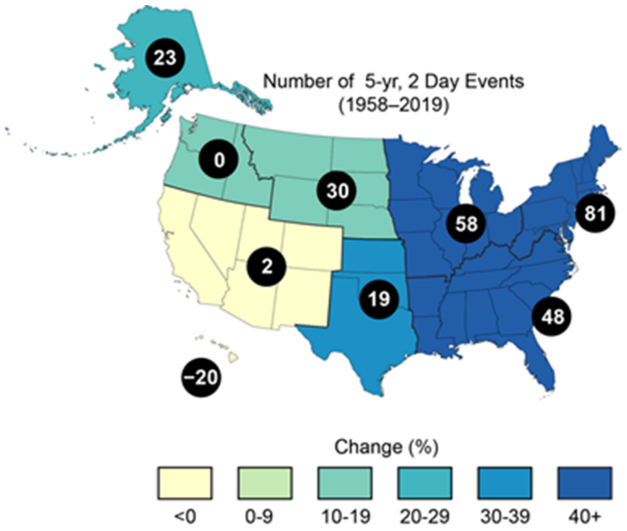

Fig. 7 Change in a metric of extreme precipitation by regions used in NCA4(USGCRP 2017). This is the number of 2-day events with a precipitation total exceeding the largest 2-day amount that is expected to occur, on average, once every 5 years, as calculated over 1958–2019. The numerical value is the percent change over the entire period. The percentages are first calculated for individual stations, then averaged over 2° latitude by 2° longitude grid boxes, and finally averaged over each NCA4 region (updated from Easterling et al. 2017).

metrics of heavy precipitation, including hourly, daily, and multi-day durations and 1- to 20-year average recurrence intervals. They also cover a range of periods, some starting as early as the beginning of the 20th Century. There are important regional differences in trends. For example, an analysis shown in the NCA4 was updated through 2019, covering the period of 1958-2019 (Figure 7). The eastern half (Great Plains) of the U.S. has experienced large (moderate) upward trends while the western U.S. has experienced no trend. Globally, the lack of data availability precludes an analysis back to the beginning of the 20th Century. Most regions with adequate data show increases in extreme precipitation since the middle of the 20th Century (Seneviratne et al. 2012; Kunkel and Frankson 2015).

Future Changes in Climate

Scientists use a wide range of observational and computational tools to understand the complexity of Earth's climate system and to study how that system responds to external forces, including human activities. Computational physics-based models of the global climate system are important tools in both the study of past changes in climate (reanalysis, e.g., MERRA-2) and to project possible future changes in climate. Today's climate models encapsulate the current understanding of the physical, chemical, and biological processes involved in the climate system, their interactions, and the performance of the climate system as a whole. They are extensively tested relative to observations and are able to reproduce the key features found in the climate of the past century. Using projections of future emissions of how GHGs may be further affected by human activities, these models are then used to project the future changes in temperature, precipitation, and other climate variables.

Future changes in global climate will depend on future atmospheric greenhouse gas concentrations. The globally-averaged CO2 concentration has increased from about 284 ppm in 1850 to 410 ppm for Sep 2018-August 2019. The current growth rate in CO2 concentration is about 0.6% per year. At that rate, concentrations would reach about 500 ppm by 2050. Under the RCP8.5 emissions pathway (high emissions scenario), the growth rate accelerates with concentrations reaching 900+ ppm by 2100.

Basic physics dictates that increases in GHG concentrations will have a warming effect, with virtual certainty, due to the increase in atmospheric absorption of infrared energy and re-emission back to Earth's surface. This increase in downwelling infrared energy flux will gradually warm the ocean surface waters, as well as the land surface. The increase in ocean surface temperatures will cause an increase in near surface absolute humidity over the oceans. Humidity can increase exponentially with temperature following the Clausius–Clapeyron relationship, by about 3.5% per °F (7% per °C) at current temperatures. This is projected to cause the summer absolute humidity levels to increase in areas where normal climate circulation patterns bring air directly from the oceans onto the land. This will increase the amount of water vapor available to precipitation-producing weather systems, leading to more extreme precipitation episodes.

Heating Degree Days (HDD) are projected to decrease in most places while Cooling Degree Days (CDD) are expected to increase (e.g., Figures 8 and 9). This change is neither expected to be uniform across the globe, nor monotonic for a given weather station. A monotonic change would imply that the given value always either increases or decreases for consecutive time steps but not both. Under a high-emissions (RCP8.5) scenario, climate zones, which are calculated from degree days, are projected to change all around the world. Recent changes in zone classifications for North America are shown in Figure 6, which compares the results of classifying areas based on data 2000-2019 vs data from 1980-1999. These historical changes in climate zones are almost uniformly towards warmer zones (i.e., lower number in the ASHRAE system). The changes are clustered at the boundaries and the pattern is particu-

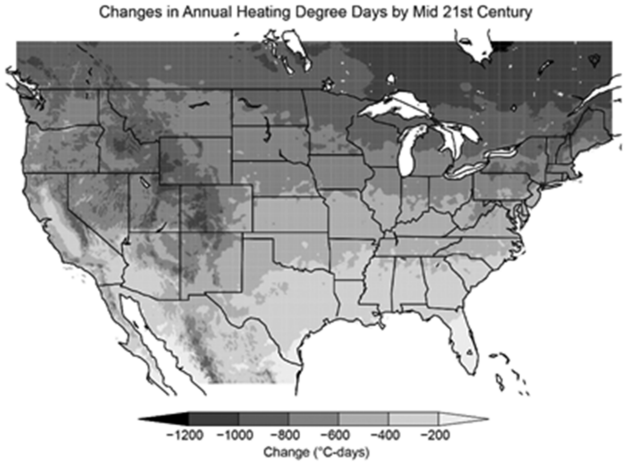

Fig. 8 Projected change in heating degree days by the mid-21st century (2036-2065) relative to 1976-2005 under a high emissions scenario (RPC 8.5).

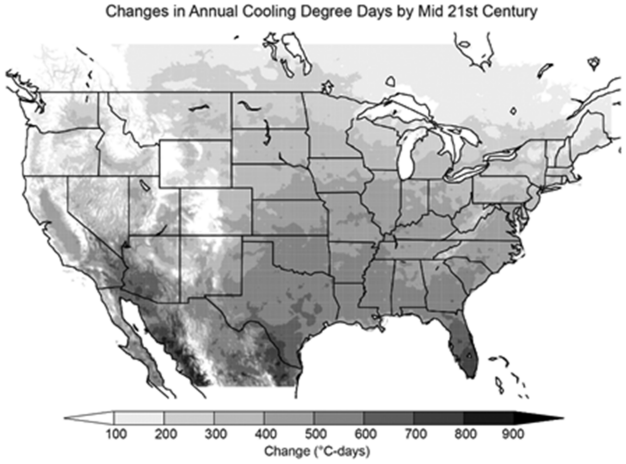

Fig. 9 Projected change in cooling degree days by the mid-21st century (2036-2065) relative to 1976-2005 under a high emissions scenario (RPC 8.5).

larly clear in central North America. To accommodate warmer climates, a new zone 0 was added in 2016 to extend the climate zone scale.

Both heating and cooling design temperatures are increasing for large numbers of stations around the world, and are projected to continue increasing. Figure 10 shows hottest and coldest daily temperatures, as well as, number of frost days and number of tropical nights under the high emission (RCP8.5) projection from 2081-2100.

The warmest daily temperature and coldest daily temperature are analogous to the design day method for sizing HVAC equipment. Figures 11 and 12 suggest designers of buildings that expect to have a service life stretching into the next decade may require larger and more flexible HVAC equipment installations. Furthermore, the frost days as very important to those who work in agriculture as a newly sprouting crop-field can be stunted due to a last frost. Tropical nights can cause productivity issues for those without access to air-conditioning and cause those with air-conditioning systems to run throughout the night.

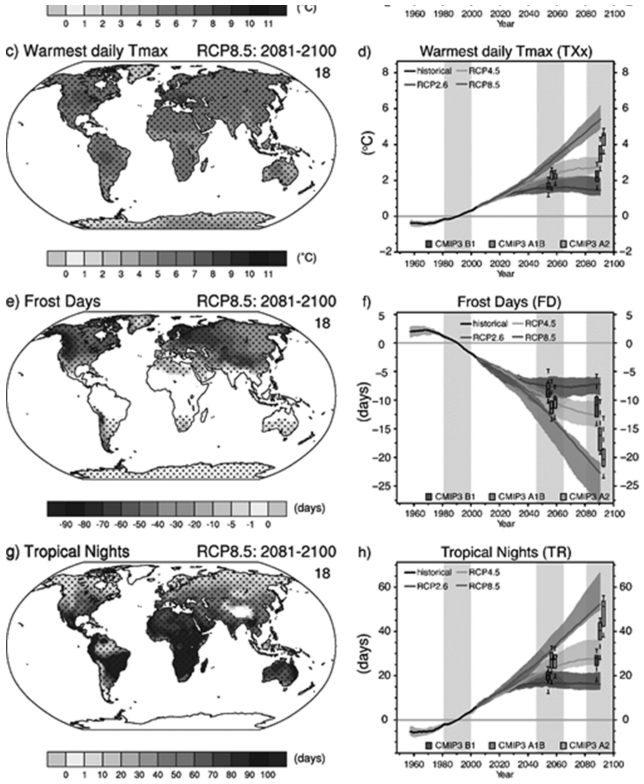

Fig. 10 CMIP5 multi-model mean geographical changes (relative to a 1981–2000 reference period in common with CMIP3) under RCP8.5 and 20-year smoothed time series for RCP2.6, RCP4.5 and RCP8.5 in the (a, b) annual minimum of daily minimum temperature, (c, d) annual maximum of daily maximum temperature, (e, f) frost days (number of days below 0°C 32 °F) and (g, h) tropical nights (number of days above 20 °C (68 °F) (Figure 12.13, IPCC 2013).

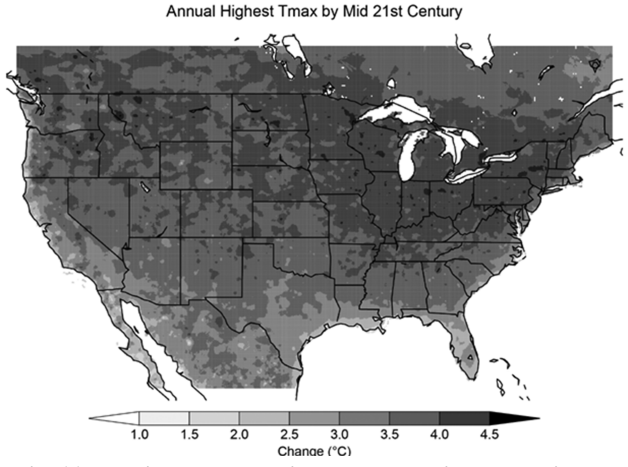

Fig. 11 Projected change in the annual highest maximum temperature by the mid-21st century (2036-2065) relative to 1976-2005 under a high emissions scenario (RPC 8.5)

For the U.S., for the high emissions scenario (RCP8.5), the annual highest maximum temperatures in North America are projected to increase by 4°F–8°F (2.2°C-4.4°C) by 2050 (Figure 11).

Licensed for single user. © 2021 ASHRAE, Inc.

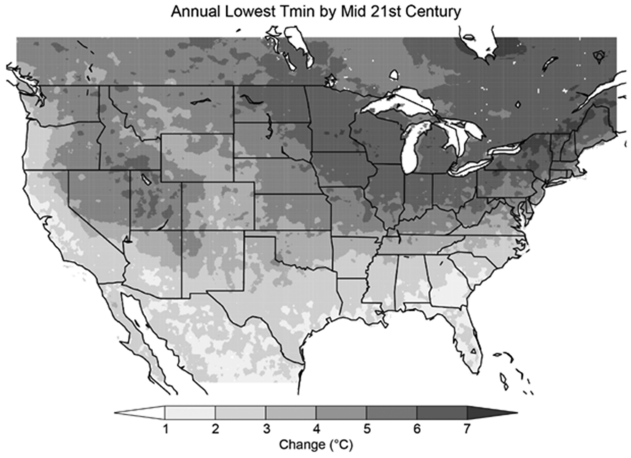

Fig. 12 Projected change in the annual lowest daily minimum temperature for 2036-2065 (relative to 1976-2005) under a high emissions scenario (RPC 8.5).

The annual lowest minimum temperatures are projected to warm by 4°F–10°F (2.2°C-5.5°C) by 2050 (Figure 12). Maps of this type for other regions are available at the National Oceanic and Atmospheric Administration (NOAA) website (www.ncdc.noaa.gov/cag/global/mapping).

Projected changes in mean precipitation changes vary considerably by region, primarily a consequence of global changes in atmospheric circulation patterns. The jet stream is projected to shift northward, with general decreases in precipitation at subtropical latitudes and increases at mid to high latitudes. The U.S. straddles this transition. Thus, increases in mean precipitation are projected for the northern U.S., but decreases are projected for the southwest. Mean precipitation has increased by about 10% over the last century in the Midwest and northeast and is projected to increase by as much as another 10% this century. In many other U.S. areas, precipitation is either projected not to change or there remains uncertainty about the direction of change (increase versus decrease). However, precipitation coming as extreme events is projected to increase substantially almost everywhere by 2050 and beyond, especially under a high emissions scenario.

Recent increases in drought in some areas, such as Australia and the western U.S., have been partially attributed to climate change. Other areas of the U.S. have not experienced increases in drought. Drought is projected to become more frequent and intense in many subtropical areas where mean precipitation is projected to decrease, including the southwest U.S. In other areas, droughts are expected to continue being a normal part of the climate and may be more intense because of higher temperatures increasing rates of soil moisture depletion (Wehner et al. 2017).

Increases in water vapor content and temperature lead to an increase in wet bulb temperature. Increases in the frequency of extreme wet bulb temperatures has already been reported around the world, e.g., northern India and eastern U.S.A. Shifts in the frequency of high wet bulb values increases cooling loads and, in the absence of cooling systems, thermal stress on humans. These changes, therefore, create a further undesirable outcome: increasing the energy used for cooling buildings, which increases their GHG emissions further.

Relative to the year 2000, GMSL is very likely to rise by 0.3–0.6 feet (9–18 cm) by 2030, 0.5–1.2 feet (15–38 cm) by 2050, and 1 to 4 feet (30–130 cm) by 2100. Future emissions pathways have little effect on projected GMSL rise in the first half of the century, but significantly affect projections for the second half of the century (high confidence). Emerging science regarding Antarctic ice sheet stability suggests that, for high emission scenarios, a GMSL rise exceeding 8 feet (2.4 m) by 2100 is physically possible, although the probability of such an extreme outcome cannot currently be assessed. Regardless of emissions pathway, it is extremely likely that GMSL rise will continue beyond 2100. For almost all future GMSL rise scenarios, relative sea level rise is likely to be greater than the global average from the U.S. Northeast to the western Gulf of Mexico.

Projected Climatic Information for Use in Building Design and Analysis

The process of creating projected weather 'input files' from Global Climate Models (GCM) suitable for use in building design and analysis is a complex process. For simulating estimated future building performance, reliable sets of future weather conditions are needed. Similarly, sizing calculations require estimates of future 'design conditions'. Currently, there are no standardized methods to integrate information about a changing climate into building and system design and analysis, but this does not preclude action and the need for professional judgment. The output from GCM can be useful for stress testing buildings and systems using multiple plausible futures. This allows a designer to test the impact of multiple plausible acute or chronic climatic events such as heat waves or gradually-increasing temperature over decades. While this section does not make specific recommendations on choosing a future climate data provider, certain aspects of the available data are discussed here. Since the outputs of GCM are used to create weather data for building design and simulation, examples are presented here for information.

A majority (64%) of the fifth Coupled Model Intercomparison Project (CMIP5) GCMs provide predictions over cells in the range of roughly 62 miles x 62 miles to 155 x 155 miles (100 km x 100 km to 250 km x 250 km) while coordinated Regional Climate Model (RCM) experiments can go down to 7.8 miles x 7.8 miles (12.5 km x 12.5 km); although individual research group simulations have gone down to 3.1 miles (5 km) or even 0.6 miles (1 km). A GCM cannot usually be used directly for building design and analysis because of its coarse resolution, it must be 'downscaled'. Downscaling is any procedure to infer higher resolution information (finer spatial scale here) from lower resolution variables or information (coarser spatial scale). There are two types of downscaling – dynamical and statistical – and regional climate models are a form of dynamical downscaling. Statistical downscaling methods inherently provide higher spatial resolution and correction of biases in the GCMs. A regional climate model uses a global climate model as its boundary conditions, and focuses on a specific region (domain), e.g., North America. This allows regional climate models to provide predictions for smaller areas, i.e., the global climate models are 'downscaled' to smaller portions of the earth. While RCMs provide higher resolution, they usually still contain some biases and it may be necessary to correct for these biases before applying to design.

Projected future time series generated by suitably downscaling GCM are estimates, not exact predictions. The distinction is that the data is intended to be indicative of the best available science - not a literal forecast for a specific time in the future. As such, it is important to treat the dates on these future time series as indicative of a broad future time period, not an exact future year. The resolution of the models and methods is not high enough to justify distinguishing between individual years, e.g. July 2048 vs 2050, or 2052. The latest model outputs from IPCC member organizations were summarized in the 5th Assessment Report (IPCC 2014a). Dynamically-downscaled simulations are made available through the CORDEX collaboration (WCRP 2017). The CORDEX collaboration uses a suite of regional climate models driven by a suite of the CMIP5 global cli-

Licensed for single user. © 2021 ASHRAE, Inc.

mate models (Taylor, Stouffer, and Meehl 2011). The available RCM-GCM combinations vary widely by region. For example, the North American region includes data for 8 RCMs driven by 6 GCMs. By contrast, the South Asia region includes 6 RCMs driven by 15 GCMs. In both cases, only selected combinations have been performed (16 of 48 possible for North America, 26 of 90 possible for South Asia). The models used data up to 2005 to simulate historical conditions and future scenarios of anthropogenic forcing to estimate from 2006 onwards. Updated projections are expected to be published with the upcoming AR6 report due in 2022. The projections data from 2006 to 2019 now provide more than a decade of additional data available to assess their accuracy.

The use of a single GCM is not an adequate approach to capture the uncertainty in future climate conditions. As a result, climate scientists use ensembles of models, i.e., the results of several models together. The results from each model are reasonable estimates because each model is based on different but sound scientific assumptions and assumptions of the evolution of external factors such as CO2 emissions. Given that the practicing designer is not expected to know the finer points of climate modeling, choosing a specific model is less useful than using all of them together, i.e., an ensemble of models (Jentsch, 2008; Barsugli 2013; Rastogi and Khan 2020). That is, given that many of the complex inputs or variables that are needed to predict the climate accurately are uncertain, a robust design needs to consider many different 'scenarios' or outcomes borne out from different evolutions of key variables.

The methods currently available to use future climate projections in design and assessment are based on two approaches: morphing and stochastic generation. Broadly, morphing is the shifting and stretching of time series of measured (historical) data with 'change factors' from suitably-downscaled GCM outputs (Belcher, Hacker, and Powell 2005). The change factors represent the expected change in a statistical value of a parameter, e.g., the average temperature for a summer month. Thus, applying a change factor to historical data from a given location 'morphs' the time series to a possible future climate for the same location. Stochastic generation is the same action on the distribution of measured data, followed by sampling of the distribution to obtain time series (Rastogi 2016, and references therein). Stretching and shifting the distribution of values from historical measurements for a given location can be considered a proxy of a changed climate. Hence, generating time series from such a changed distribution allows for the creation of several possible future 'weather' conditions for the future climate in that same location. The various implementations of each approach all seek to maintain the 'climate signature' compared to the reference measured data for relative change modeling. Climate signature is a term used to encompass the within-day, diurnal, and seasonal variations and patterns unique to a given local climate that should be maintained in future projections, in the absence of information to the contrary. Methods for estimating future design conditions are still unresolved, but work is ongoing to correct this.

Professional bodies such as the Chartered Institution of Building Services Engineers (CIBSE) (e.g., CIBSE 2005; Hacker, Capon, and Mylona 2009; Shamash, Metcalf, and Mylona 2014; Bonfigli et al. 2017), and researchers (e.g., Belcher, Hacker, and Powell 2005; Crawley 2008; Eames, Kershaw, and Coley 2011; 2012; Jentsch et al. 2013; Patton 2013; Sustainable Energy Research Group 2013; Eames 2016; Rastogi 2016; Herrera et al. 2017) have proposed methods to develop future weather input files for use in building design and analysis. As methods to develop and use projected time series advance and move toward standardization, ASHRAE members can train to manage professional practice risk, as other professional societies are doing for their members (ASCE 2015; CIBSE 2005; Bonfigli et al. 2017; Nicol 2013; AASHTO 2020; AIA 2020).

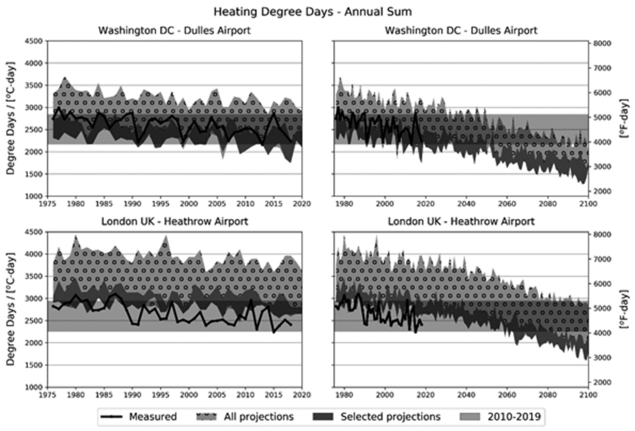

Fig. 13 Annual sum of HDD from Heathrow Airport, London, and Dulles Airport, Washington, D.C.: historical (solid black line), 2010-2019 range (light grey band), and global/regional climate model projections (hatched and dark grey fills). The downward trend is neither steep nor monotonic, but unmistakably downward in both the measurements and model projections. The climate projections show variation in the projected warming, which is to be expected given the divergence in assumptions that underlie them. By the middle of the 21st Century, it becomes increasing likely that measured values will fall outside the recent historical range.

Using Recent Measured Data

While recent historical data is a reasonable estimate of expected near-future conditions, it is not a good estimate of conditions over decades, or the usual service lives of buildings and systems (Ayyub 2018; Maxwell et al. 2018). For example, Figures 13 and 14 show annual sums of heating and cooling degree days from Dulles Airport in Washington, D.C., and Heathrow Airport in London, UK.

As a thought experiment, the near-future estimates from 2010, i.e., made up of data from 2000-2009, are plotted alongside "near-future" data (2010-2018), recent historical measured data, and global climate model projections. The band of data from 2000-2009 encompasses both measured values from 2010-2017 and projected values up to about 2030 (those projections were made in 2006). Coverage starts to decrease after that, i.e., more model outputs are outside the grey band.

Summary

Multiple indicators show that substantial global warming has occurred since the late 19th Century, with most of that warming over the past 50 years. It is likely warmer now, on average, than at any time in at least the past 1,700 years. Exhaustive research has examined potential causes of this warming. The increase in greenhouse gas concentrations, along with the modifying effects of increasing concentrations of atmospheric particles, along with smaller effects from changes in land use, is the only plausible cause that is consistent with the observed data, and the physics that governs the climate system.

It is virtually certain that greenhouse gas concentrations, particularly CO2, will continue to rise over this century. Changes in methane (CH4) are also important and are likely to continue to increase for at least the next few decades (USGCRP 2017). The increasing concentrations of CO2 and CH4 are largely related to the use of fossil fuels. It may take decades for non-carbon-based sources of energy to replace most of the production currently based primarily on fossil fuels. As a result, it is virtually certain that global tempera-

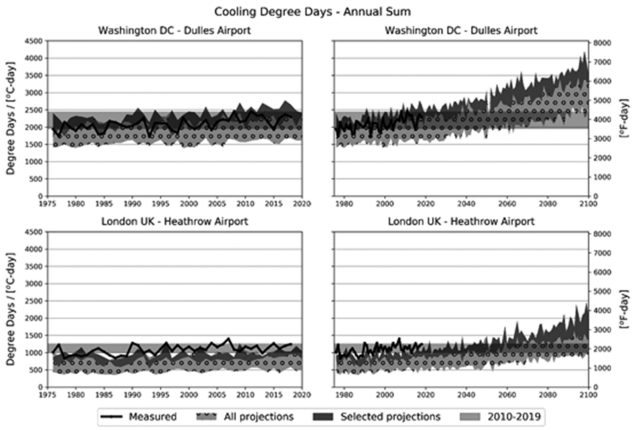

Fig. 14 Annual sum of CDD from Heathrow Airport, London, and Dulles Airport, Washington, D.C.: historical (solid black line), 2010-2019 range (light grey band), and global/regional climate model projections (hatched and dark grey fills). The upward trend is neither steep nor monotonic, but unmistakably upward in both the measurements and model projections. The climate projections show variation in the projected warming, which is to be expected given the divergence in assumptions that underlie them. By the middle of the 21st Century, it becomes increasing likely that measured values will fall outside the recent historical range.

tures will continue to rise. Local changes in temperature can deviate temporarily from the global trend because of natural climate variability. Infrastructure and building systems designed only using historic climatic information may, therefore, not meet their intended service life.

2. MITIGATING CLIMATE CHANGE

Limiting climate change requires a substantial and sustained global effort to significantly reduce anthropogenic (human-made) GHG emissions rates to avoid further warming and long-lasting changes in all components of the climate system. The consequences of a lack of timely action threaten the health and well-being of both current and future generations. Climate change mitigation (simply called "mitigation" from now on) is an intentional human intervention to reduce the sources or enhance the sinks of GHGs in order to limit the magnitude of future warming. The ultimate goal of mitigation is to stabilize GHG concentrations in the atmosphere at a level that avoids dangerous changes in the climate system (Wuebbles et al. 2017). Any changes in climate that are not avoided through mitigation must be considered by engineers as factors to adjust to through climate change adaptation. Mitigation can be understood as "avoiding the unmanageable", whereas adaptation can be understood as "managing the unavoidable" (Bierbaum et al. 2007).

The international response includes a mitigation goal to limit global temperature rise in this century to 2°C (3.6°F) above pre-industrial levels and to pursue efforts to limit the temperature increase even further to 1.5°C (2.7°F). There are clear benefits to keeping warming to 1.5°C (2.7°F) rather than 2°C (3.6°F) or higher. Limiting global warming to 1.5°C (2.7°F)compared to 2°C (3.6°F) is projected to reduce increases in ocean temperature and well as associated increases in ocean acidity and decreases in ocean oxygen levels. Consequently, limiting global warming to 1.5°C (2.7°F) is projected to reduce risks to marine biodiversity, fisheries, and ecosystems, and their functions and services to humans, as illustrated by recent changes to Arctic sea ice and warm-water coral reef ecosystems (IPCC 2018). However, global temperature has already increased 1.0°C (1.8°F)above pre-industrial levels and global GHG emissions show no signs of peaking. Total annual GHG emissions reached a record high of 55.6 GtCO2e in 2018. (Olivier 2019) Global GHG emissions need to be sharply lower than 2018 levels by 2030 - approximately 25% and 55% lower to put the world on a least-cost pathway to limiting global warming to 2°C(3.6°F) and 1.5°C (2.7°F) respectively (UNEP 2018). Beyond 2030, limiting global warming to 1.5°C requires CO2 emissions to be reduced to net zero globally around 2050 (IPCC 2018).

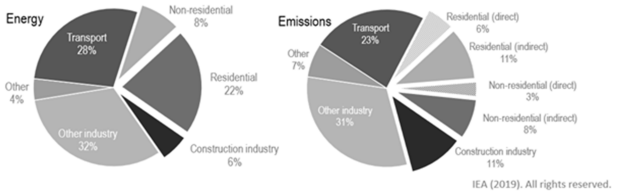

Fig. 15 Global share of buildings and construction final energy and emissions, 2018 (Figure 2, IEA, 2019)

Residential and commercial building construction and operations accounted for the largest share of both global final energy use (36%) and energy-related CO2 emissions (39%) in 2018 (Figure 15) (IEA 2019a; 2019b). Additional to the energy used for direct building construction and operations, sequestered carbon is released from plants and soils due to site preparation. Since buildings are responsible for a large portion of GHG emissions, they are a major focus of mitigation efforts. This is driving innovation to decarbonize existing and new buildings. GHG emissions associated with the burning of fossil fuels can be categorized as either direct emissions, where systems and end uses are powered or heated directly by fossil fuels, or indirect emissions, for end uses that use electricity. In residential and commercial buildings, direct emissions are primarily from space heating, service hot water and cooking. Industrial buildings also use fossil fuels for manufacturing processes. The indirect emissions from building electricity use are largely associated with lighting, HVAC loads (heating, cooling, fans and pumps), service hot water, plug loads, and refrigeration. Figure 16 and Figure 17 show the relative percentages of total energy consumption (commercial) and electric energy contributions to indirect emissions (residential) by building end use in the U.S.

An additional source of emissions from buildings relates to unintended release of Fluorinated Gases (F-gases) used as refrigerants or as expanding agents for some types of foam insulations. Some refrigerants used in HVAC&R applications (CFCs, HCFCs and HFCs) are a direct source of either GHG emissions, ozone depleting agents or both when they are accidentally released into the atmosphere through system leakage or deliberately released instead of recycled at end-of-life. Some low-GWP refrigerants may negatively impact system energy efficiency, in turn raising the energy cost of space conditioning.

This section covers a myriad of mitigation strategies. The combined potential of mitigation efforts in the building sector are tremendous. It is estimated that by 2050 a combination of aggressive efficiency measures, electrification, and high renewable energy penetration can reduce the CO2 emissions from building operations in the U.S. by 72-78% relative to 2005 levels (Langevin, Harris, and Reyna 2019).

The ASHRAE GreenGuide—Design, Construction, and Operation of Sustainable Buildings, 5th Edition (ASHRAE 2018a) provides extensive guidance for designers and building operators to mitigate climate change by: modifying their methods, designs and

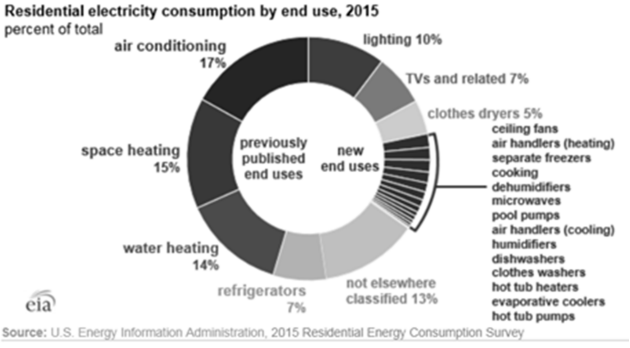

Fig. 17 U.S. Residential electricity consumption by end use, 2015.

operations for new buildings; employing passive designs; appropriately retrofitting existing buildings by improving energy efficiency; constructing buildings using low-embodied energy materials; and eventually operating buildings employing only Renewable Energy Systems (RES). RES can be building integrated, onsite, or offsite. The pursuit of building electrification for both new and existing buildings—using electric-powered systems and equipment instead of combustion-based systems will assist in easing the transition from GHG emitting fossil fuel sources to RES. It is also important to reduce the use of Fluorinated Gases (F-gases) having high Global Warming Potential (GWP) ratings while maintaining system efficiency. These steps are addressed briefly in this section.

Reduce Carbon Emissions by Design and Construction

Advancing building energy codes continue to raise minimum energy consumption baselines, but the building industry can no longer rely on improved efficiency standards alone in order to realize global climate change mitigation goals. Design teams need to investigate all available site and building passive strategies from the onset of the building concept to minimize the greenhouse gas emissions associated with new or major remodel construction project. Passive design measures aim to maintain thermal conditions and indoor air quality, not through energy system efficiencies, but through avoidance or reduced reliance on active design solutions, the energy consuming mechanical and electrical systems.

Designers (as well as the building operators) need a tool for rating a building's energy use to use as a goal for optimizing energy efficient design (and operation). Energy consumption in buildings is commonly quantified using site Energy Use Intensity (site EUI) which is calculated by converting all electricity and fossil fuel energy consumed on site in one year to kBTUs (kWh) and dividing by the building conditioned floor area, giving units of kBTU/ft2-yr (kWh/m2-yr). Source EUI is determined by converting site energy to source energy based on the blend of energy sources used to generate electricity. Design teams establish target EUI goals consistent with researched values for minimum EUI of similar building types. Building carbon emissions are quantified by applying emissions factors to site energy consumption based on the carbon intensity of the regional electric grid.

For successful mitigation and decarbonization, building design teams should use an integrated design process (ANSI/MTS 1.09 WSIP Guide 2007, ASHRAE Standard 209-2018 - Energy Simulation Aided Design for Buildings except Low-Rise Residential Buildings). An integrated design approach front-loads the design process and schedule, allowing for clarity about the observed and expected climatic conditions for the intended service life, and facilitates aggressive energy efficiency and passive strategies. Optimizing energy efficiency is one of the most cost-effective approaches to reducing emissions and should be pursued both during building design and as part of operations and maintenance. The integrated design process encourages early team collaboration in order to maximize low cost and high impact energy design choices, when design changes are least expensive. The design team can utilize advanced energy modeling and life cycle cost assessment tools to assess which investment strategies will realize the highest rate of return over the life of the building. ASHRAE Standards 209-2018 - Energy Simulation Aided Design for Buildings except Low Rise Residential Buildings and ANSI/ASHRAE/ICC/USGBC/IES Standard 189.1: Standard for the Design of High-Performance, Green Buildings Except Low-Rise Residential Buildings provides the technical framework for climate change mitigation within the vertical built environment.

A large portion of GHG emissions from buildings is associated with the construction process. Sources of embodied carbon emissions include cement production, manufacturing and transportation of building materials to name only a few. A complete cradle-to-grave embodied carbon assessment includes GHG emissions associated with materials extraction, manufacturing, transportation, construction, maintenance and end-of-life disposal. Annually, embodied carbon is responsible for 11% of global GHG emissions associated with energy consumption (Architecture 2030 2018). Since embodied carbon emissions are associated with the construction phase of a building, they constitute a much higher percentage of total emissions in new buildings than in existing buildings that have experienced years of operation. It is projected that the embodied carbon emissions of global new construction projects will constitute 49% of total building emissions for period 2020-2050, while the operational carbon from energy consumption makes up the remaining 51%. Since the GHG emissions from existing buildings are comprised almost entirely of operational carbon, renovations and upgrades to existing buildings will usually result in lower emissions than the new construction of an energy-efficient building. It is estimated that new buildings that are 30% more efficient than average performing existing buildings can take anywhere between 10-80 years to offset the embodied emissions from construction with the lower operational emissions from more efficient systems (NTHP 2011).

Embodied carbon reduction strategies fall into five general categories: (1) low-carbon materials; (2) material minimization and material reduction strategies; (3) material reuse and recycling strategies; (4) local sourcing and transport minimization; and (5) construction optimization strategies (Akbarnezhad and Xiao 2017).The highest share of embodied energy for buildings comes from struc-

Licensed for single user. © 2021 ASHRAE, Inc.

tural materials, primarily concrete and steel, accounting for roughly 60% of total embodied energy. The use of structural wood should be considered, and the total cement content of building materials should be reduced and optimized. Materials databases and embodied carbon software (such as the free Embodied Carbon in Construction Calculator "EC3" tool) have recently become available to assist design teams with calculating and tracking the life cycle GHG emissions associated with their building projects.

Net zero or near zero buildings demonstrate the maximum level of climate change mitigation that can be achieved through building design and operation. These buildings consume minimal energy as limited by energy efficiency opportunities and are then powered using carbon-free sources of energy. Environmentally friendly building design has progressed beyond simply reducing energy use. Architects, engineers and other building professionals now aspire to achieving net zero buildings or even negative zero buildings where the building can supply more energy to the grid than it consumes overall. While there are many names, variations and building certifications for it, net zero building design generally accounts for, and eliminates as much as possible, the carbon emissions from a building over its service life. At a minimum, net zero buildings are designed to use as little energy as possible, and source the remaining energy needs from renewable, carbon-free sources. To be considered net zero, direct carbon emissions are usually eliminated completely. This is achieved by forbidding onsite fossil fuel combustion (with the possible exception of emergency generators at least for the near future) and by selecting only electrically powered components and systems for all end uses since future energy will be either be provided as grid or mini-grid electricity or through Photovoltaic Solar or Wind generated on-site electricity. Net zero carbon buildings additionally track the carbon emissions associated with building construction (including embodied energy) and operation and, until energy is produced only by renewable energy, offset the carbon emissions by generating a surplus of renewable energy on site or procuring carbon offsets through a certified carbon offset program. Net zero design fiscal prioritizations include

- **Step 1:** Assess and prioritize the site and community resources such as optimizing zoning for renewable energy and building proximity to local or community waste heat resources.
- **Step 2:** Maximize architectural passive design strategies to meet property and occupant needs. Passive design strategies can include site planning, building orientation and massing, envelope tightness to reduce infiltration, continuous insulation, window and daylighting optimization, and designing a building to take advantage of natural ventilation and solar thermal opportunities.
- **Step 3:** Anticipate decarbonization of electric grids. Emphasize electric systems or provide dual fuel systems.
- **Step 4:** Maximize mechanical, electrical and plumbing system efficiencies. Incorporate heat recovery systems, advanced controls, and
- **Step 5:** Offset remaining energy needs with on-site or purchased off-site renewable energy to reduce the facility's carbon footprint.

Perform Deep Energy Retrofits of Existing Buildings

While local adoption of high-performance building energy codes is critical for mitigating GHG emissions in new construction, addressing energy efficiency within the existing building stock is equally important to cap and reduce GHG emissions. It is expected that 71% of the total building area worldwide in 2015 will exist in the year 2030 (54% in 2050). For developed industrial nations, these predicted percentages increase to 83% for 2030 (73% for 2050) (https://www.statista.com/statistics/731858/projected-global-building-floor-area-growth-by-region/ accessed 05.19.20). To limit the global average temperature rise to less than 3.6°F (2°C) above preindustrial levels by 2030, the rate and depth of efficiency savings must increase in existing building retrofits. Improvements to existing buildings can help mitigate climate change through whole building retrofits, equipment and system efficiency improvements and one-to-one system replacements. Energy savings of 50-90% have been achieved in existing buildings throughout the world through deep retrofits (IPCC 2014a). It is recommended that decision makers identify and document both the current and future energy resources, onsite and external, as the basis of design for mitigation and adaptation. An additional consideration in planning retrofits is to consider that the climate is already changing and will continue to do so. Thus, designers must consider the effect of the changing climate on the magnitude of efficiency gains, as well as unexpected outcomes due to changes such as increased humidity, when retrofitting and upgrading existing buildings.

To date, voluntary conventional retrofits like lighting or isolated system upgrades have been encouraged through tax incentives and favorable financing, providing a relatively quick return on investment. To achieve global climate change mitigation goals, however, existing building retrofits need to increase in frequency and achieve more savings. Policy changes will be required to increase the frequency of deep energy retrofit investments. Deep energy retrofits are defined here as renovation investments that provide 50% or more energy savings and require a whole building approach. ASHRAE publishes resources for conducting energy audits on existing buildings, e.g., Standard 211-2018: Standard for Commercial Building Energy Audits. Retrofit advisors should be cognizant of changing design assumptions such as energy resources, policy mandates and local climate change, as well as potential financial and legal risks and insurance impacts to those that do not undertake retrofits. The overall goal of deep energy retrofits in the global existing building stock is to reduce the use of fossil fuels, transition to carbon free energy and improve resilience to climate change.

Retrofitting historic buildings requires extra care since applying some modern Energy Efficiency Measures (EEMs) may actually cause damage. Prior to retrofitting historic buildings for energy efficiency, see ASHRAE Guideline 34-2019: Energy Guideline for Historic Buildings. Historic buildings can also serve as examples for applying passive methods for heating, cooling and ventilating to newer buildings.

Reduce Carbon Emissions from Building Operations

An obvious aspect to reducing energy use and consequently carbon emissions involves the building operators' diligence in properly and timely maintaining equipment and their systems. Building operations as well as occupant behavior and expectations are also necessary components to climate mitigation strategies. Efforts can be established for leveraging energy load demand response, and energy storage opportunities. This includes sub-metering and scheduling of plug-in loads to curb increasing occupant energy demands for charging personal equipment. However, two of the most important practices are continuous building system monitoring and periodic retro-commissioning.

Building system monitoring provides verification that efficient construction and renovation projects delivered their intended performance. Monitoring of facility energy consumption and system operations is the foundation for Measurement and Verification (M&V), which promotes accountability and compliance with energy efficiency policy directives. It is a useful tool to identify when and where performance issues occur in buildings over time, as they inevitably do. Continuous building system monitoring uncovers faults before they cause significant energy loss. Unplanned increases/decreases in pressures or flow rates that may lead to equipment failures or indicate clogged filters, unintentionally closed (or open) valves, over-ridden controls—all reduce efficiency and increase carbon emissions. Periodic retro-commissioning of the buildings' equipment and systems is highly recommended to further

Licensed for single user. © 2021 ASHRAE, Inc.

ensure that the equipment and systems are functioning at their highest levels.

Renewable Energy Sources (RES) and Building Electrification

To reach the ultimate goal of eliminating GHG emissions from buildings, RESs must replace fossil fuel sources. RESs include, but are not limited to solar, wind, ocean wave energy, hydro, and geothermal. Electricity can be produced using any of these RESs and is preferred, e.g., in today's market, solar electricity (produced with Photovoltaic Solar Panels) is economically better for heating domestic water than using thermal solar collectors. To provide for intermittent RES, storage of electricity can be provided at the utility level with lithium ion batteries, compressed air, elevated water storage and large-scale chemical flow batteries. At the building or minigrid level, RES-produced electricity can be stored in batteries and mechanical fly-wheels. For this reason, and those cited below in respect to interfacing with the current grid, it is critical to convert all buildings to be able to use electricity to provide HVAC&R, as well as domestic hot water.

Electrification is a core driver of decarbonization in tandem with energy efficiency and the reduction of the emissions of the existing electric grid (2018 ACEEE Summer Study on Energy Efficiency in Buildings). Changes in the availability and usage of RES has already begun, however it is not currently widespread. In the meantime, building electrification can directly replace on-site fossil-fuel systems with grid-provided electrically powered systems. When the electricity for these systems is provided from RES, the usage is shifted entirely from fossil fuels to carbon-free sources.

In the U.S., electricity demand is projected to increase by 3%–9% by 2040 under the higher scenario and 2%–7% under the lower scenario. This projection includes the reduction in electricity used for space heating in states with warming winters, the associated decrease in heating degree days, and the increase in electricity demand associated with increases in cooling degree days (NCA, 2018). These projections do not include the building industry's anticipated fuel switching from fossil fuels to full electrification.

One of the biggest challenges to building electrification is the selection (in new buildings) or the conversion (in existing buildings) of electrically-powered space heating systems in lieu of fossil fuel-based systems. Natural (or propane) gas- and oil-fired furnaces and hot water boilers are ubiquitous systems with relatively low first costs. Two alternatives to consider are electric resistance heating and heat pumps. Electric resistance heat has a low first cost and its site energy use is more efficient than the use of on-site fossil fuels (100% vs. 80-90+%). However, the associated energy costs are often significantly higher based on the relative cost of electricity per BTU (kWh) of heat. This high cost of using resistance heat may or may not change as RESs ramp up to replace fossil fuel generated electricity. Heat pumps are viable today and typically provide a sound alternative to electric resistance heating. There are several types of heat pumps and, depending on the type and configuration, either hot air or hot water can be supplied for heating with the added benefit of also supplying space cooling. Chilled beams can use the hot water for space heating or cold water for space cooling (provided that humidity levels are controlled so dew points are not reached). Heat pumps can also provide hot service water and thus replace hot water tanks. Heat pump equipment efficiency is higher than either electric resistance or non-electric fossil fuel systems, with a typical heating Coefficient Of Performance (COP) value of 3 to 4.

Cost of Avoiding GHG Emissions

The costs and activities associated with the removal or avoidance of a unit of greenhouse gas emissions is referred to as abatement. Marginal Abatement Cost (MAC) curves plot out the marginal costs of achieving emissions reductions in order from the lowest- to highest-cost technology or policy. A well-known example is one from McKinsey (McKinsey & Company 2009), though its cost estimates are out of date in 2020. Recent estimates of abatement costs using cleaner electricity generation technologies are shown in Table 2 (Gillingham and Stock 2018). The estimates compare the cost per ton of CO2 abated by replacing existing coal-fired electricity. GHG emission reduction technologies can also be evaluated based on their implementation within government policies and programs. Estimated ranges of the marginal abatement costs of several recently-enacted policies are shown in Table 3 (Gillingham and Stock 2018).

Table 2 New source generation costs when compared to existing coal generation (Gillingham and Stock 2018).

Technology	Cost Estimate ($2017/ton CO_2)
Onshore Wind	25
Natural Gas Combined Cycle	27
Utility-scale Solar Photovoltaic	29
New Natural Gas with Carbon Capture and Storage	43
Advanced Nuclear	59
Coal Retrofit with Carbon Capture and Storage	85
New Coal with Carbon Capture and Storage	95
Offshore Wind	105
Solar Thermal	133

Source: Author's calculations updating methodology from Clean Air Task Force (2013) based on Energy Information Administration estimates from the 2018 Annual Energy Outlook. CCS refers to carbon capture and storage technology. Costs are projected for facilities that come on line in 2022. Costs do not incorporate federal renewable tax credits.

Table 3 Static costs of policies based on a compilation of economic studies (Gillingham and Stock 2018).

Wind Energy Subsidies	2-260
Clean Power Plan	11
Gasoline Tax	18-47
Methane Flaring Regulation	20
Reducing Federal Coal Leasing	33-68
CAFE Standards	48-310
Agricultural Emissions Policies	50-65
National Clean Energy Standard	51-110
Soil Management	57
Livestock Management Policies	71
Concentrating Solar Power Expansion (China & India)	100
Renewable Fuel Subsidies	100
Low Carbon Fuel Standard	100-2900
Solar PV Subsidies	140-2100
Biodiesel	150-420
Energy Efficiency Programs (China)	250-300
Cash for Clunkers	270-420
Weatherization Assistance Program	350
Dedicated Battery Electric Vehicle Subsidy	350-640

Notes: Rounded to two significant digits. The authors have converted all estimates to 2017 dollars for comparability. See Appendix Table A-1 for sources and methods. CO_{2e} denotes conversion of tons of non-CO_2 greenhouse gases to their CO_2-equivalent based on their global warming potential.

Refrigerants and Fluorinated Gases (F-Gases)

Fluorinated gases (F-gases) are categorized as CFCs, HCFCs and HFCs. Historically, F-gases have been used as refrigerants and expanders for foam insulation. Release of F-gases into the atmosphere cause either ozone layer depletion and/or contribute to GHG emissions. The remainder of this subsection primarily addresses refrigerants with regard to GHG emissions and their mitigation.

Refrigerants are the working fluids in refrigeration, air-conditioning, and heat-pumping systems. Both F-gases and none-F-gases are used as working fluids, but those which are of concern with regard to climate change are the F-gas refrigerants. They become an environmental concern when they are leaked or released into the

Licensed for single user. © 2021 ASHRAE, Inc.

atmosphere, which may occur at various points throughout the life cycle of equipment, from manufacturing to installation, operation, servicing and ultimately to decommissioning at end of life. Minimizing all refrigerant releases from systems is important not only because of direct environmental impacts, but also because refrigerant charge losses lead to suboptimal operation and decreased efficiency.

In 1987, all 197 UN member countries agreed to phase out the production of Ozone-Depleting Substances (ODS), including CFCs and HCFCs, under the Montreal Protocol (2017 ASHRAE Handbook—Fundamentals). As a result, HFC refrigerants were widely adopted as ODS substitutes, but have since been identified as potent GHGs with orders of magnitude more impact on the climate than carbon dioxide (CO2). The Global Warming Potential (GWP) of a GHG is an index describing its relative ability to trap radiant energy compared to CO2 (R-744), typically using a 100-year Integration Time Horizon (ITH) to sum up its cumulative effect. Metrics for climate impact of refrigerant emissions are reported as the equivalent mass of CO2 that would have the same impact, in lb (kg) CO2eq (IPCC 2013). Due to their high GWP values, HFCs have been subject to increasing regulations. In 2016, the Kigali Amendment to the Montreal Protocol was developed, which included a timeline for the mandated phase-down of HFCs for developed and developing nations (UNEP 2016). The Kigali Amendment went into effect for ratified countries on January 1, 2019. As of July 2020, 100 nations have ratified the Kigali Amendment. Action under the Amendment will help reduce HFCs and thus avoid global warming up to 0.72 oF (0.4oC) by 2100 (UNEP 2016).

In the U.S., the EPA's Significant New Alternatives Policy (SNAP) program, which was established to evaluate and regulate ozone-depleting substances and substitutes, moved many HFCs from the acceptable list to the unacceptable list and added new lower GWP alternatives to the acceptable list under SNAP Rule 20 and Rule 21. A complete list of unacceptable and acceptable refrigerants under these rules may be found at www.epa.gov/snap/snap-regulations. However, in 2017 the U.S. Court of Appeals for the District of Columbia ruled that the EPA did not have the authority to regulate HFCs, and the rules were overturned (Mexichem Fluor, Inc. vs. Environmental Protection Agency 2017). A growing number of states from the U.S. Climate Alliance, a coalition of states committed to reducing GHG emissions, have since announced intentions to regulate higher GWP HFCs. Proposed regulations include, but are not limited to, establishing the vacated SNAP rules at the state level.

Indices have been developed to measure the total environmental impact of HVAC&R systems. The Total Equivalent Warming Impact (TEWI) of an HVAC&R system is the sum of direct refrigerant emissions from leaks expressed in terms of CO2-eq, and indirect emissions of CO2 from the system's energy use over its service life (Fischer 1993). Life Cycle Climate Performance (LCCP) is a more comprehensive evaluation of global warming impacts from direct and indirect emissions. In addition to the greenhouse gases measured by TEWI, LCCP adds direct and indirect emissions associated with the energy and chemicals required in manufacturing the refrigerant, and the energy and materials associated with end-of-life disposal (IIR, 2015). Additional information on refrigerants can be found in Chapter 29 of this volume.

Lower GWP refrigerant alternatives include natural refrigerants, unsaturated HFCs such as hydrofluoro-olefins (HFOs) and hydrochlorofluoro-olefins (HCFOs), and refrigerant blends with two or more components. HFOs and HFO/HFC blends have been developed as lower GWP alternatives to HFC refrigerants. Some HFOs are also GHGs but their GWPs are drastically lower than those of HFCs. Naturally occurring substances such as ammonia (NH3, R-717), CO2, and hydrocarbons are non-halocarbon refrigerants with GWP100 values between 0 and 5 (i.e., these gases have a GWP between 0 and 5 times the GWP of CO2). Note that from a regulatory perspective there are the values accepted for use by the Montreal Protocol which are quite often rounded to zero; from a purely scientific perspective, some refrigerants have an extremely small ODP value but not exactly zero ODP. There is no crisp definition of when "essentially zero" is considered zero for regulatory purposes. Table 4 shows the latest scientific assessment values for atmospheric lifetime, ozone depletion potential (ODP), and GWP100 of refrigerants being phased out under the Montreal Protocol and of their replacements.

Table 4 Refrigerant Environmental Properties. Atmospheric lifetime, ODP and GWP100 from Table A-1 of (Fahey et al. 2018) except where indicated.

[a]Chapter 29, 2017 *ASHRAE Handbook—Fundamentals*
[b]IPCC 2013

Geoengineering Technologies

Annual global GHG emissions continue to increase, or at best are starting to level off. Limiting warming to 1.5°C (2.7°F) requires strictly limiting future carbon emissions. The total amount of allowable carbon emissions (the "carbon budget") is small relative to annual emissions rates. Estimates for the remaining carbon budget for a 66% chance of limiting warming to 1.5°C (2.7°F) range from negative (meaning the carbon budget has already been exceeded) to only 15 years of current emissions. These estimates imply that if

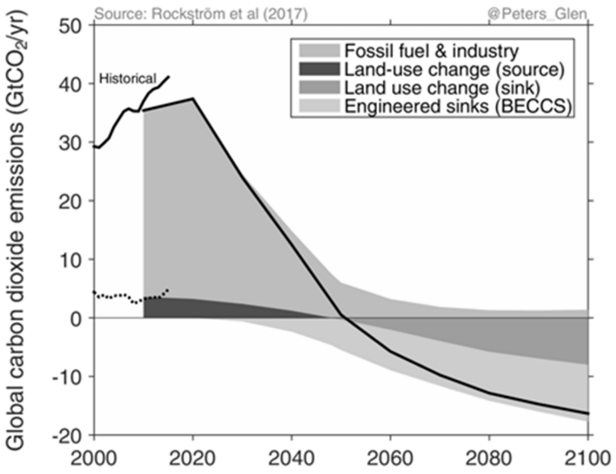

Fig. 18 Global CO2 emissions (fossil fuels, industry, & land-use change) in a "well below 2°C" scenario from MESSAGE. It is possible to split the net emissions (black line) into gross positive and gross negative emissions.

GHG emissions are not rapidly reduced, the remaining carbon budget will be used up by around 2035 at the latest and emissions rates would need to drop to zero to avoid dangerous levels of warming. The mitigation measures that engineers and building design professionals are most likely to focus on are those that reduce GHG emissions. However, there are additional strategies for mitigating global warming. Carbon Dioxide Removal (CDR), also known as Greenhouse Gas Removal (GGR) or simply Carbon Removal (CR) refers to techniques for removing CO2 from the atmosphere and durably storing it through anthropogenic activities (IPCC 2018). Solar Radiation Management (or Modification) (SRM) involves deliberate changes to the albedo of the Earth system, with the net effect of increasing the amount of solar radiation reflected from the Earth to reduce the peak temperature from climate change (The Royal Society 2009). Both CDR and SRM can be lumped into a broader category of technologies known as geoengineering. Broadly, geoengineering is any deliberate large-scale intervention in the Earth's climate system, in order to moderate global warming. (The Royal Society.) As we rapidly burn through the remaining carbon budget, the temptation to implement and rely on geoengineering technologies will be strong. Engineers and building design professionals should understand that geoengineering is very risky and largely untested, and is not a replacement for long-term GHG emissions reductions.

CDR technologies are also known as negative emissions technologies (NETs). All potential emissions pathways that limit global warming to 1.5°C (2.7°F) or even 2.0°C (3.6°F) rely on CDR to some degree to compensate for residual emissions and achieve net negative emissions after a period of temporary overshoot of the target. Most potential pathways include a significant contribution of Bioenergy with Carbon Capture and Storage (BECCS) and/or afforestation and reforestation (AR). BECCS is the process of extracting bioenergy from biomass and capturing and storing the carbon, thereby removing it from the atmosphere (Obersteiner 2001).

The role of BECCS and/or other NETs can be seen in the graph of global CO_2 emissions (fossil fuels, industry, and land-use change) in a "well-below-2°C" scenario in Figure 18, based on a simple carbon cycle and climate model.

The graph shows that annual emissions from fossil fuels and industry must rapidly decrease relative to the solid black historical trend line, and annual emissions from land use changes must decrease relative to the dotted black historical trend line. Land use changes need to become net carbon sinks. In combination with BECCS, these negative emissions offer a pathway to net zero emissions in 2050 as indicated by the solid black line.

Summary

Mitigating the impact of human activities on climate has been, and should continue to be, a major technical and professional obligation for building designers and operators. While this section laid out actions that can be taken today, it is important to consider these in the context of a climate that has already changed and will continue to do so. Actions taken by building designers and operators, as cited above, will have a positive effect in reducing GHGs and OPS and thus slowing down the negative aspects of climate change. In support of ASHRAE's mission and vision, it is imperative to be aware of the context within which buildings should be designed and operated, and the evolution of energy supply and distribution, disaster risks, and changing expectations.

3. ADAPTING TO CLIMATE CHANGE

Adaptation is the process of adjustment to actual or expected climate which seeks to moderate or avoid harm or exploit beneficial opportunities (AR5, IPCC 2014b; AR 6 forthcoming). Adaptation implies accounting for the magnitude and direction of future climate change in design and operation, guided by risk tolerance and appetite. Depending on the design brief, the vulnerability of a building's occupants, the ability to suspend normal activities during extreme events, and site considerations such as urban density, the designers should assess the impacts of different climate projections for a given location on their proposed design or specification. To design building envelopes and HVAC systems, adaptation to climate change is about the "when" and "how", since it acknowledges that change is already occurring and that there is risk in not adapting (McKinsey Global Institute 2020).

An ASHRAE Framework for Risk-Aware Practice

The design of building envelopes, HVAC, and other systems that dictate the indoor environment and energy performance of a building over its decades-long service life presents a choice to take an adaptive response (IPCC 2014b). Across design disciplines, adaptation is a risk management function (ASCE 2015; WFEO 2015; AIA 2020), addressing both the threats and opportunities of climatic change.

The current state of the art approaches are risk-informed decision-making frameworks. Best practice combines an asset-based approach, where better knowledge of the asset is acquired through a vulnerability assessment of its historic vulnerabilities and recovery/resilience potential (Stéphane Hallegatte et al. 2012), with a characterization of relevant forward-looking climate information which affects the asset. The combination seeks to optimize what is known from an object's past and then identifies what needs further investigation for the plausible conditions that the asset will experience during its intended service life. This approach requires bringing together expertise in asset management, adaptive management and designing and valuation of options and flexibility as climate science is not the sole singular source for answers (Stephane Hallegatte, Rentschler, and Rozenberg 2019; Haasnoot et al. 2013; Ayyub 2018). This section encourages ASHRAE designers and operators to look upon adaptation as an exercise in the realistic assessment of risk based on the best available information.

Adaptation and Related Terms

Designers also benefit by understanding adaptation and its interconnected relationship with mitigation and resilience. As stated earlier, both mitigation and adaptation are required. There are co-

Licensed for single user. © 2021 ASHRAE, Inc.

benefits and tradeoffs depending on the location, and the needs and objectives of the client/ occupant (Adger et al. 2013). Recommendations for improving the energy efficiency or environmental impact of buildings for mitigation exist in other ASHRAE documents such as Standard 189 and Standard series 90. As explained in the previous section, mitigation reduces the impact of buildings and systems on the environment, while adaptation anticipates the changes that are already occurring and will continue to do so.

Adaptation is also related to resilience but is not equivalent to it (Keenan, Hill, and Gumber 2018; Weaver et al. 2013). Between resilience and adaptation, there are significant differences in the time and spatial scales, and in operational expectations. Resilience seeks to maintain and recover to a known expected base state (status quo) of performance and operation after a disturbance. Adaptation is a process of transformation from one state to another usually in response to external factors (a state/outcome). Adaptation demands anticipatory thought (Klein, Snowden, and Pin 2011) and treats the new base state as the norm informed by value sets (Adger et al. 2009; Wong-Parodi, Fischhoff, and Strauss 2015). Recently, some define resilience as including adjustments over longer time frames, but this is more accurately defined as adaptation (Keenan 2018; Lempert et al. 2018; Wong-Parodi, Fischhoff, and Strauss 2015; Lama, Becker, and Bergström 2017).

Chronic vs Acute Impacts of Climate Change

Chronic impacts are slow changes in mean values or 'normals' at a location that create different prevailing conditions than the historical record. Acute impacts are an outcome of these, i.e., a change in the frequency or intensity of occurrence of high-intensity, extreme or near-extreme events that typically last over some finite duration and will likely cause acute but time-limited distress to human health and buildings (Diffenbaugh 2020). An example of a chronic impact is the change in climate zones shown in Figure 6. For example, a new zone was added to the ASHRAE climate zone classifications in 2016 for zones warmer than the previous warmest zone (ASHRAE Standard 169-2013: Climatic Information for Building Design). An acute impact is the increase in heat wave potential in places that have moved to a warmer climate zone. The opportunity for designers and operators to advance adaptation spans both the chronic and acute impacts of climatic change. Climate-conscious design and analysis through simulation can inform forward-looking adaptive building design.

Chronic changes in climate, i.e., changes in normals often change several metrics relevant to building and HVAC design and analysis. An example of how chronic changes might impact buildings is as follows. Most cooling systems are designed for one of 3 different possible cooling design conditions corresponding to the 0.4%, 1%, or 2% design temperatures and humidity for the building's location. Simplifying somewhat, a design for the 0.4% cannot meet the load for 0.4% of the time each year on average, or roughly 35 hours a year (0.4% of 8760). For a cooling system, that could be roughly 1 hour per day for the 30 hottest days of the summer. An HVAC system installed today can be expected to have a functional life of 25-30 years, and temperatures will continue to increase over that period. If the 0.4% percentile temperature value comes to correspond instead to the 2% value, i.e., the distribution of temperatures shifts towards warmer temperatures, the 35 hours become 175.2 hours (2% of 8760). In this case, a building will be faced with 3-4 hours a day of non-attainment over 58-44 days. For example, for a system designed in 1986 using weather data from Dulles Airport, the mean 0.4% design temperature for 1975-85 was 27.68°C (81.82°F). For the same system, the mean 2% temperature in the last decade of its service life (2006-2016) was 27.91°C (82.24°F). This is not a theoretical exercise for most locations, especially urban ones where Urban Heat Island (UHI) has exacerbated the impacts of climate change. While UHI, as the increase in temperature due to urbanization is known, is distinct from climate change, the two effects interact. The impact is both to exacerbate acute phenomena such as heat waves, and affect strategies for heat mitigation such as night-time cooling. For more information on UHI and its impact see Chapter 14, Climatic Design Information, of this volume.

Chronic changes in climate are stressors for buildings and systems, i.e., they increase the overall stress or demand on them. Acute events such as heat waves are also expected to continue to increase in frequency and duration, shocking mechanical systems and the ability of equipment to maintain thermal health. Changes in seasonal weather trends and sub-seasonal episodic weather, e.g., intensity and duration of heat waves, sustained high night-time temperatures and humidity, extreme rainfall, drought, etc., affect near-term operational performance, occupant comfort and health and long-term energy efficiency (Katharine Burgess and Foster 2019). Similarly, increased particulate matter (due to increase in wildfires) and organic contamination (due to increased flooding) negatively affects air quality and equipment performance, while increasing required maintenance and decreasing equipment efficiency (ASHRAE Guideline 29-2017: Guideline For The Risk Management Of Public Health And Safety In Buildings).

Impacts on Envelope-Driven Loads

The global climate is already changing, and this has many impacts relevant to designers and operators. Impacts include the necessity to plan for future conditions while managing the impact of climate change on existing operations. These changes are evident in several metrics relevant to envelope design, such as changes in Degree Days and climate zone classifications. Besides these indicators, there are numerous impacts of climate change that affect envelope-driven loads as well as occupant health and comfort both directly and indirectly, such as increases in periods of intense heat, significantly warmer 'typical' summers, etc. In other words, envelopes designed without consideration of changing probabilities of acute events and changes in climate normals may cause significant heat stress, overheating, and unplanned increases in envelope loads.

Impacts on HVAC Systems

HVAC systems or components typically have an intended service life of approximately 30 years. Table 3, Ch. 38 of the 2019 ASHRAE Handbook—Applications presents estimated median service lives in excess of 22-25 years for most components (Owen 2019b). Designs developed and executed based on historical climate assumptions pose a risk to the occupants as they can overestimate the system's capabilities and capacity to maintain safe indoor environmental conditions (Maxwell et al. 2018). This includes sizing of trunk ducts, cooling loop mains, and adequate space to accommodate the expansion or other changes to the mechanical equipment, the type of utility-supplying systems, or other elements with a long service life. For such systems, designers must consider how the design is able to adapt when, not if, conditions change (USACE 2018). This should not be taken as a recommendation to increase or decrease system capacity - if anything, systems are already overdesigned. Rather, it is encouragement to use passive and active resilience measures which prioritize flexibility, modularity, and expandability as part of a robust HVAC system design in changing conditions. ASHRAE design methods already favor buildings and HVAC systems that would perform robustly in a variety of conditions, including some extreme conditions. What designers need to understand is that the external climate, a critically important boundary condition of these design methods, has changed and is changing.

Existing vulnerabilities in HVAC design, and buildings that depend on them, are made worse by the observed and expected changes in climate (Maxwell et al. 2018). Multiple factors are driving these vulnerabilities. These include poorly maintained and degraded buildings and systems as well as historic and cultural

Licensed for single user. © 2021 ASHRAE, Inc.

assets which were not designed for the changing climatic conditions. In urban areas, the increase in population and changes in land use stress not only the occupant demand on HVAC systems but the base operating conditions due to heat island effect (IPCC 2014a; Maxwell et al. 2018; Dahl, Kristina et al. 2019). For example, HVAC equipment failure during an extreme event like a wildfire or heat wave can lead to dangerous conditions being exacerbated by the inability to escape outdoors. Urban areas often report higher nighttime temperatures than would be expected from their meso-climatic (regional) context. This is largely due to the urban heat island effect and has effects such as a reduction in the effectiveness of nighttime active and passive free cooling. This impact too is being exacerbated as climate change causes more frequent heat waves and increased average temperatures.

Impacts on Indoor Air Quality

The performance of mechanical systems is directly and indirectly impacted by both chronic and acute events of climate change and other extreme events. Actual outdoor conditions that sufficiently deviate from design conditions can lead to difficulty in controlling indoor conditions to the detriment of Indoor Air Quality (IAQ). For example, the predicted increases in outdoor absolute humidity (discussed in the Climate Science section) can overburden a system and increase the incidence of high indoor humidity and potential for microbial growth (Kalvelage, Dorneich, and Passe 2015). As climate normals shift, the mechanical systems may not be sized adequately to properly manage increased sensible and latent loads (Wang and Chen 2014; Qi, Lu, and Yang 2012; Watkins and Levermore 2011). If the prevailing wind direction changes enough, separation distances and orientations between building exhaust and outdoor air intakes from the original system design and assumptions may cease to be adequate. While failure of HVAC&R systems can have potentially serious outcomes for occupant health and wellbeing, the potential impacts are even greater for mission critical facilities, as interruption of their operation can have severe implications and knock-on effects on services and relief efforts. Indirect impacts of climate change on building IAQ include the effect of an increase in outdoor air pollution (particulates and gas-phase compounds) on air treatment and handling systems. This could result in non-attainment of a variety of outdoor air contaminants within the scope of the US EPA NAAQS (PM2.5, PM10, SO2, CO, O3, NO2, lead) and the inability of the HVAC system to adequately provide mitigation or remediation. At best, this would require more intensive and/or frequent maintenance to adapt to the increased pollutant loads.

Disaster events are acute challenges for any building and may cause irreparable damage to the building's capability to maintain the indoor air quality. The weather events of concern include, but are not limited to: flooding, extreme heat (higher peak day-time temperatures, particularly when accompanied by high humidity, and higher night-time temperatures and humidity), extreme cold (ice and/or heavy snow), hurricanes/tornados, wind-driven rain, mudslides, and wildfires. An example of the acute risk posed by a disaster is the increased risk of carbon monoxide exposure and poisoning. During such events, filtration systems can become contaminated, clogged, wet, or structurally damaged. Open systems like cooling towers can become sources of infectious microorganisms such as legionella. Penetration through the building envelope can lead to serious HVAC&R load problems, humidity/mold/moisture issues, and pest infestations. Disease epidemics are a major concern if occupants must Shelter-in-Place in large populations or if temporary disaster relief centers are set up in large facilities that were not designed to accommodate such events. Large increases in particulate matter from wildfires, structure fires, or volcanic events can significantly deteriorate the outdoor air quality due to airborne particulate matter and dangerous gases (Guan et al. 2020). During such times, loss of electricity without a backup power source can worsen IAQ in enclosed spaces, especially those without the ability to take passive backup measures. Damage to building drainage systems (storm and sewer) can cause uncontrolled moisture within buildings that may result in proliferation of bacteria and fungi colonies.

The ASHRAE Position Document on Infectious Aerosols (ASHRAE 2020) contains numerous control measures such as dilution ventilation, specific in-room flow regimes, room pressure differentials, personalized and source capture ventilation, filtration, and Ultraviolet Germicidal Irradiation (UVGI). Some examples of strategies to implement in early planning, new construction, or retrofits, depending on performance requirements and location, are given here:

- **Contaminant Removal Technologies (CRT)** – minimum MERV13 filtration, Gas-Phase VOC filters, HEPA filtration, automatic roll filter mechanisms, electrostatic precipitator (ESP) systems, gas-phase filtration, cyclone collectors, etc.
- **Bypass systems** to minimize energy consumption during normal use that must provide adequate CRT protection during events.
- **IAQ Performance Strategy (IAQP)** – performance-based approach to reducing outside air levels coupled with high efficiency cleaning systems, especially during cooling/heating design days and weather-related events, while maintaining acceptable air quality (ASHRAE Standard Series 62: Ventilation for Acceptable Indoor Air Quality).
- **Dedicated Clean Air Systems (DCAS)** – High-performance, easily-maintainable systems will be required, especially during wildfire events where particulate levels will overwhelm filter banks.
- **Pressurization** – During events such as disease epidemics or wildfires, pressurization strategies inside buildings will be necessary.
- **Shelter-In-Place (SIP)** – All facilities should have plans to shelter-in-place during disasters to ensure life safety and acceptable air quality.
- **UVGI or UV Cleaning** – Can be used to disinfect surfaces, airstreams (SIP), and upper air. May also be used on cooling coils to keep heat transfer surfaces energy efficient & disinfected. Duct & upper air applications can be applied for infectious control in emergencies to make a facility resilient, especially for an emergency center.
- **CO2, IAQ, and moisture monitoring** (VOCs, particulates, etc.), forecasting, and reacting to events. As monitoring systems improve in reliability and coverage, the availability of real-time information on indoor conditions during an event can significantly improve outcome-based control and planning.
- **IAQ, Water, & Bacterial Management Plan** – including flood resistant materials, barriers, & wet/dry flood-proofing, water disinfection systems, etc.

Operational Management and Design for Smoke Migration Risk from Wildfires

Wildfires threaten structures in cities or produce smoke that causes visibility and health problems for people living and working many miles away. Buildings that are in or adjacent to wildfire-prone areas need the capability to operate at a slight positive pressure to keep contaminants out, and to help exhaust air systems to function properly. It is not recommended to eliminate or substantially reduce the outdoor air supply in order to reduce exposure to smoke. For preparedness of an existing facility or prevention in a new facility, a qualified HVAC technician or engineer must assess the building mechanical systems for this incident type and determine, in writing, the amount of outside air and filtration necessary to prevent negative pressurization of the building, and to sufficiently ventilate any hazardous processes in the building (such as enclosed parking garages

Licensed for single user. © 2021 ASHRAE, Inc.

or laboratory operations) (EPA 2016, Appendices A and D: Identification and Preparation of Cleaner Air Shelters for Protection of the Public from Wildfire Smoke). At this time, there is not an ASHRAE standard which specifically addresses the operational and design needs to manage this risk.

Existing Professional Activities

Technical societies around the globe are developing practices and methods to integrate climatic projections and climate-based risk analysis in the design of infrastructure, e.g., American Institute of Architects (AIA), American Society of Civil Engineers (ASCE), American Association of State Highway Transportation Officials (AASHTO), and Chartered Institution of Building Services Engineers (CIBSE). ASCE has issued a Manual of Practice which emphasizes adaptive management and the use of engineering options analysis (Ayyub 2018), which is a relevant and transferable approach. The AIA has developed and launched training on these topics for mid- career professionals as well (AIA 2020). The reliance on stationarity and use of backward-looking or historical data and information is often insufficient for design or performance in conditions that are changing and will continue to change. Currently, these efforts are spearheaded by hydrology and hydraulics, and structural, architectural and urban design. This advancement is propelled by many factors. These include availability of actionable science based on climatic information of high confidence and likelihood, the long service life of the asset or system and the professional judgment which recognizes that current designs can underestimate risk as the future is not expected to be like the past.

On the other hand, existing professional education and licensing of engineers and architects, building codes and zoning do not require the integration of changing climatic conditions (Maxwell et al. 2018), except in a few U.S. cities (e.g., New York City) and countries (Canada, U.K., E.U.). Designers can instead heed the advice of the World Federation of Engineering Organizations by following the Seven Principles of the Model Code of Practice, particularly No. 7, planning for service life, and No. 8, using risk assessment for uncertainty and No. 9, monitoring legal liabilities (WFEO 2015).

Design Opportunities and Strategies

Licensed design professionals inform investment decisions by qualifying and quantifying the risk over the service life of an asset (Maxwell et al. 2018) and by designing for reliable performance in changing conditions (Hallegatte et al. 2012). This important role applies to both capital investment and capital reinvestment for risk-informed decisions (Katherine Burgess and Rapoport 2019). This spans the finance, insurance and appraisal sectors (Maxwell et al. 2018). These sectors are also driven to respond to stakeholder demands to disclose climate risks across their portfolios (TCFD 2017). It is recognized that insurance is not a protection against a "reduction in an asset's liquidity or depreciation in value" (Katherine Burgess and Rapoport 2019). Designs which provide owners with surety of energy, water and sewage conveyance systems (ISC 2016) allow " a chance to fight obsolescence and an opportunity to differentiate their assets even more in vulnerable areas" (Katherine Burgess and Rapoport 2019; S. H. Holmes and Reinhart 2013; S. H. Holmes, Rajkovich, and Baker 2017). Envelope design which integrates forward-looking climatic information is a preventive stance by designing to avoid or minimize damage, impairment (FASAB 2013), loss of life, shortening of the asset or component life (Glassman and Reinhart 2013; Katherine Burgess and Rapoport 2019), loss of capital or stranded assets (Keenan, Hill, and Gumber 2018). In addition to climate risk-informed investment management, designs which can adapt to changing conditions promotes business or mission continuity which has high value in the near term (NIBS 2018).

The service life of buildings can be extended by designing and specifying robust building envelopes, materials and applying methods of envelope assembly which can withstand or adapt to stress from extremes in temperature or moisture. Existing practice and recommendations must be examined against the backdrop of a change climate, for example through the use of simulation with projected climate information and similar 'what-if' analyses. An approach which uses decision scaling and stress testing can enhance robustness. First, the designer can identify the exposure and sensitivity of a system or component and then determine if the climatic parameter is a plausible and dominant factor driving vulnerability, e.g., in consideration of the likelihood of flooding, locating mechanical and electrical equipment rooms where it will likely be negatively affected by flooding. The designer can then determine whether the design has coping capacity (stress test) or needs to be redesigned to reduce vulnerability (Ray and Brown 2015). These include standard efficiency recommendations such as air tightness, insulation and thermal bridging both above and below grade and management of building pressurization. Also important are the long-term thermal transfer capability of ground source heat pumps (Kharseh et al. 2015) and managing for changes in water vapor drive (direction/quantity/seasonal timing) as measured by vapor pressure (Maxwell et al. 2018; Ch. 25, Owen 2019a) . In some locations, a change in water vapor drive can determine not only long-term HVAC performance of the envelope but the exposure of structural systems to moisture (corrosion) or the degradation of other materials in the assembly such as insulation and or sealants. Correct building pressurization is also connected to long term durability as well as managing acute extremes. For some locations, frequent and intense spikes in particulate matter due to wildfires, as mentioned above, will require filtration design and operation adjusted to these new extreme conditions (e.g., more frequent cleaning of filters).

It is recommended to employ passive means to offset increased expected temperatures in place of simply increasing chiller sizes, e.g., improved shading and intelligent use of ventilation, including maximum ventilation at night when relative temperatures (and humidity levels) between the ambient and interior are favorable. CIBSE studies have shown that combining high thermal mass combined with intelligent ventilation gives the best performance (CIBSE 2005; Nicol 2013). Adaption also means specifying multiple units of equipment in place of specifying a larger single unit and providing space for adding equipment to increase cooling capacity in the future as needed.

Depending on the usage of a building and the criticality of each system, the building components and systems are designed to function under some predefined extreme environmental or usage conditions. During these acute events, i.e., episodes of extreme or near-extreme weather, systems must maintain operational performance. However, changes in the frequency and intensity of these events shifts the boundaries on what is considered a design extreme event, and under what conditions failure is accepted. A building designed to fail over historical 99th percentile temperature, so roughly only 1% of the time over a long-enough operating life, is likely to fail more often because the historical 99th percentile temperature is now 95th percentile, i.e., to be exceeded 5% of the time over a sufficient period of record. Design for acute events includes system redundancy or modular design to handle expected extremes in support of energy or water surety for critical facilities. This includes design for adequate ventilation and filtration to manage increased particulate matter such as pollen or dust or to manage acute incidents such as the migration of smoke from distant wildfires while maintaining adequate building pressurization. To support essential facilities and business or mission continuity, HVAC design professionals can develop methods for load reduction or shifting. This could help to better manage interruption of utilities for passive survivability and thermal resilience.

Licensed for single user. © 2021 ASHRAE, Inc.

With the adaptation parameters and systems capabilities listed above, designers are well-positioned to integrate forward-looking climatic information into HVAC performance criteria as existing ASHRAE practices and methods already use climatic parameters today (GAO 2016). Given the expected service life, the need for flexibility and adaptability to changing conditions, and understanding the risk of reliance on historic (backward looking) information and assumed stationarity within the available information, there are useful approaches available.

Resources for Adaptation

As this section emphasizes through its discussion of risk, risk-aware engineering and professional judgment, the future climate is not exactly predictable. Good estimates exist but can only be made precise incrementally as the science of climate improves. In addition, the impact of economic, technological, and policy factors means that there will always be uncertainties in climate projections. However, designers have to act now. Just as the investment and the energy sector have found (TCFD 2017; Gold 2019), relying solely on typical data can border on professional negligence as it actively ignores current actionable evidence. While design for future climate appears optional or in some settings might even be discouraged due to liability concerns, global professional practice is changing. In such a situation, statistical science suggests that averaging projections over multiple scenarios improves accuracy, if plausible scenarios are chosen (Jentsch et al. 2013; Barsugli et al. 2013; Rastogi and Khan 2020). How can one go about selecting these scenarios? There are two responses to this, both discussed in the climate science section above:

- Use historical data – though this is a defensible approach for near-future outcomes, it has predictive limitations.
- Use a realistic weather generator – a generator modifies historical data with the outputs of climate change models. Two approaches were described earlier – morphing and stochastic generation. Each of these can produce multiple plausible estimates of future years or a statistically-derived 'future typical year' (FTMY).

Existing ASHRAE Resources

Existing ASHRAE resources unfortunately rely solely on historical data. Since 2001, ASHRAE has published up-to-date climatic design conditions based on historical data in ASHRAE Standard 169 Climatic Data for Building Design Standards. These standards contain climatic information for around the world collected and summarized for use in design and are updated every three years. Designers should use the most recent versions of the standards in their work and evaluate the most current forward-looking information to design building systems.

Moving forward, standards must evolve to account for the changing conditions described in this chapter. They must address design and its relationship to the climate, including historically observed conditions and the expected change in conditions, especially extremes in intensity, duration and frequency (GAO 2016). The standards development revision cycle is lengthy and complex. Yet, ultimately, it informs the development of building codes that can be adopted by local jurisdictions. It is therefore incumbent on professional societies to ensure that their standards are reasonably forward-looking.

4. CONCLUSION

This chapter has laid out the evidence of climate change, and recommendations for designers to integrate the mitigation of, and adaptation to, climate change. It has discussed the impacts of climate change on buildings and systems, and the design challenges and opportunities these represent. A framework for adaptation was laid out, along with resources for designers seeking to act on the arguments and recommendations presented in this section.

This chapter will end with the following call-to-action (WFEO 2015):

Embrace uncertainty in design and use professional judgment in designing for changing conditions.

Communicate with clients to reach an understanding of climate risk and what it means for the operation and the intended service life of their investment. Document your communication.

Use projected design conditions when designing and specifying building assemblies and systems, especially if they are more extreme than those based on historical data. However, employ passive methods and provide multiple units instead of a single chiller, with allotted space for future additional equipment. Take care not to oversize equipment.

Use future climate projections for simulating the performance of these systems to inform design decisions, specifically to determine sensitivity and stress-test using plausible scenarios.

Continuously evaluate the updated information and data based on the current science.

ASHRAE's direct interest in and concern regarding greenhouse gases and climate change is reflected in its activities in heating, ventilating, air conditioning and refrigerating (HVAC&R) technologies and applications. HVAC&R systems contribute to greenhouse gas emissions in terms of refrigerant emissions and CO2 emissions associated with the energy needed for operating buildings and building systems. ASHRAE's direct interest in occupant health and safety within the built environment drives the Society's commitment to research, educate, advocate and respond to occurring climate change with the intent to guide resilient infrastructure, building systems and community designs. It is imperative that ASHRAE and its members play a critical role in mitigating and adapting to climate change.

5. GLOSSARY

Anthropogenic: Made by people or resulting from human activities. Usually used in the context of emissions that are produced as a result of human activities.

Carbon (dioxide) Capture and Storage (sequestration) (CCS): A process in which a relatively pure stream of carbon dioxide (CO2) from industrial and energy-related sources is separated (captured), conditioned, compressed and transported to a storage location for long- term isolation from the atmosphere.

Carbon dioxide equivalent (MMTCO2Eq): A metric measure used to compare the emissions from various greenhouse gases based upon their global warming potential (GWP). Carbon dioxide equivalents are commonly expressed as "million metric tons of carbon dioxide equivalents (MMTCO2Eq)." The carbon dioxide equivalent for a gas is derived by multiplying the tons of the gas by the associated GWP. MMTCO2Eq = (million metric tons of a gas) * (GWP of the gas).

Carbon Dioxide Removal (CDR): Carbon Dioxide Removal methods refer to a set of techniques that aim to remove CO2 directly from the atmosphere by either (1) increasing natural sinks for carbon or (2) using chemical engineering to remove the CO2, with the intent of reducing the atmospheric CO2 concentration. CDR methods involve the ocean, land and technical systems, including such methods as iron fertilization, large-scale afforestation and direct capture of CO2 from the atmosphere using engineered chemical means. Some CDR methods fall under the category of geoengineering, though this may not be the case for others, with the distinction being based on the magnitude, scale and impact of the particular

Licensed for single user. © 2021 ASHRAE, Inc.

CDR activities. The boundary between CDR and mitigation is not clear and there could be some overlap between the two given current definitions (IPCC, 2012b, p. 2). See also Solar Radiation Management (SRM).

Carbon footprint: The total amount of greenhouse gases that are emitted into the atmosphere each year by a person, family, building, organization, or company. A persons carbon footprint includes greenhouse gas emissions from fuel that an individual burns directly, such as by heating a home or riding in a car. It also includes greenhouse gases that come from producing the goods or services that the individual uses, including emissions from power plants that make electricity, factories that make products, and landfills where trash gets sent.

Chlorofluorocarbons (CFC): (1) Generally, any of several compounds composed of carbon, fluorine, and chlorine, used chiefly as refrigerants and as blowing agents in plastic foams. Compare to fluorocarbon; halocarbon. (2) A fully halogenated (no hydrogen remaining) halocarbon containing chlorine, fluorine, and carbon atoms.

Confidence: The validity of a finding based on the type, amount, quality, strength, and consistency of evidence (such as mechanistic understanding, theory, data, models, and expert judgment); the skill, range, and consistency of model projections; and the degree of agreement within the body of literature.

CO2-equivalent emission: The amount of carbon dioxide (CO2) emission that would cause the same integrated radiative forcing, over a given time horizon, as an emitted amount of a greenhouse gas (GHG) or a mixture of GHGs.

Extreme weather event: An extreme weather event is an event that is rare at a particular place and time of year. Definitions of rare vary, but an extreme weather event would normally be as rare as or rarer than the 10th or 90th percentile of a probability density function estimated from observations. By definition, the characteristics of what is called extreme weather may vary from place to place in an absolute sense. When a pattern of extreme weather persists for some time, such as a season, it may be classed as an extreme climate event, especially if it yields an average or total that is itself extreme (e.g., drought or heavy rainfall over a season).

F-gases (fluorinated gases): Powerful synthetic greenhouse gases such as hydrofluorocarbons, perfluorocarbons, and sulfur hexafluoride that are emitted from a variety of industrial processes. Fluorinated gases are sometimes used as substitutes for stratospheric ozone-depleting substances (e.g., chlorofluorocarbons, hydrochlorofluorocarbons, and halons) and are often used in coolants, foaming agents, fire extinguishers, solvents, pesticides, and aerosol propellants. These gases are emitted in small quantities compared to carbon dioxide (CO2), methane (CH4), or nitrous oxide (N2O), but because they are potent greenhouse gases, they are sometimes referred to as High Global Warming Potential gases (High GWP gases).

Global warming: Global warming refers to the gradual increase, observed or projected, in global surface temperature, as one of the consequences of radiative forcing caused by anthropogenic emissions.

Global Warming Potential (GWP): An index developed to provide a simplified means of describing the relative ability of a chemical compound to affect radiative forcing, if emitted to the atmosphere, over its lifetime in the atmosphere, and thereby to affect the global climate. Radiative forcing reflects the factors that affect the balance between the energy absorbed by the earth and the energy emitted by it in the form of longwave infrared radiation. The GWP is defined on a mass basis relative to carbon dioxide. The GWP for a compound must be calculated up to a particular integrated time horizon, for example, 20, 100, or 500 years. The time horizon most widely accepted is 100 years (GWP100).

Halocarbon(s): A hydrocarbon derivative containing one or more of the halogens bromine, chlorine, or fluorine; hydrogen also may be present.

Halogenated Chlorofluorocarbon (HCFC): Fully halogenated chlorofluorocarbon is one in which all of the hydrogen atoms are replaced by chlorine and fluorine atoms. Atmospheric lifetimes of fully halogenated chlorofluorocarbons are long (75 years for CFC 11 and 111 years for CFC 12).

Heat island: An urban area characterized by temperatures higher than those of the surrounding non-urban area. As urban areas develop, buildings, roads, and other infrastructure replace open land and vegetation. These surfaces absorb more solar energy, which can create higher temperatures in urban areas.

Ice core: A cylindrical section of ice removed from a glacier or an ice sheet in order to study climate patterns of the past. By performing chemical analyses on the air trapped in the ice, scientists can estimate the percentage of carbon dioxide and other trace gases in the atmosphere at a given time. Analysis of the ice itself can give some indication of historic temperatures.

Indirect emissions: Indirect emissions from a building, home or business are those emissions of greenhouse gases that occur as a result of the generation of electricity used in that building. These emissions are called "indirect" because the actual emissions occur at the power plant which generates the electricity, not at the building using the electricity.

Infrared Radiation (IR): Range of electromagnetic radiation wavelengths greater than those of visible light and shorter than those of microwaves; generally between 0.8 micrometer and 1 millimeter. IR originates from either incandescent or nonincandescent hot bodies or from flames. The energy is used as a means of direct heat transfer from the source to the object(s) to be heated without materially heating the intervening air.

Intergovernmental Panel on Climate Change (IPCC): The IPCC was established jointly by the United Nations Environment Programme and the World Meteorological Organization in 1988. The purpose of the IPCC is to assess information in the scientific and technical literature related to all significant components of the issue of climate change. The IPCC draws upon hundreds of the world's expert scientists as authors and thousands as expert reviewers. Leading experts on climate change and environmental, social, and economic sciences from some 60 nations have helped the IPCC to prepare periodic assessments of the scientific underpinnings for understanding global climate change and its consequences. With its capacity for reporting on climate change, its consequences, and the viability of adaptation and mitigation measures, the IPCC is also looked to as the official advisory body to the world's governments on the state of the science of the climate change issue. For example, the IPCC organized the development of internationally accepted methods for conducting national greenhouse gas emission inventories.

Kigali Amendment: The Kigali Amendment is an amendment to the Montreal Protocol on Substances that Deplete the Ozone Layer. It was adopted by the 28th Meeting of Parties to the Montreal Protocol on 15 October 2016 in Kigali, Rwanda. The Amendment adds powerful greenhouse gases hydrofluorocarbons (HFCs) to the list of substances controlled under the Protocol to be phased down.

Likelihood: Uncertainty expressed probabilistically (in other words, based on statistical analysis of observations or model results or on the authors' expert judgment). (USGCRP 2018)

Milankovitch cycle: The episodic nature of the Earth's glacial and interglacial periods within the present Ice Age (the last couple of million years) have been caused primarily by cyclical changes in the Earth's circumnavigation of the Sun. Variations in the Earth's eccentricity, axial tilt, and precession comprise the three dominant cycles, collectively known as the Milankovitch Cycles for Milutin Milankovitch, the Serbian astronomer and mathematician who is

Licensed for single user. © 2021 ASHRAE, Inc.

generally credited with calculating their magnitude. Taken in unison, variations in these three cycles creates alterations in the seasonality of solar radiation reaching the Earth's surface. These times of increased or decreased solar radiation directly influence the Earth's climate system, thus impacting the advance and retreat of Earth's glaciers. It is of primary importance to explain that climate change, and subsequent periods of glaciation, resulting from the following three variables is not due to the total amount of solar energy reaching Earth. The three Milankovitch Cycles impact the seasonality and location of solar energy around the Earth, thus impacting contrasts between the seasons.

Ozone Depletion Potential (ODP): A numerical quantity describing the extent of ozone depletion calculated to arise from the release to the atmosphere of one kilogram (2.2046 lb) of a compound relative to the ozone depletion calculated to arise from a similar release of the refrigerant R-11. The calculation is an integration of all known potential effects on ozone over the whole time that any portion of the compound could remain in the atmosphere.

Ozone Depleting Substance (ODS): A family of man-made compounds that includes, but are not limited to, chlorofluorocarbons (CFCs), bromofluorocarbons (halons), methyl chloroform, carbon tetrachloride, methyl bromide, and hydrochlorofluorocarbons (HCFCs). These compounds have been shown to deplete stratospheric ozone, and therefore are typically referred to as ODSs.

PgC: A Petagram (Pg), also known as a Gigaton (Gt), is equal to one quadrillion (1,000,000,000,000,000 or 1015) grams. Because there are a thousand grams in a kilogram, and a thousand kilograms in a tonne (also known as a metric ton), we can see that a Petagram is equal to a trillion (1,000,000,000,000) kilograms or a billion (1,000,000,000) tonnes. For those who prefer pounds, knowing that one kilogram is equal to 2.205 pounds tells us that one Petagram equals about 2.2 trillion pounds.

Radiative forcing: The change in net downward radiative flux at the tropopause after allowing for stratospheric temperatures to readjust to radiative equilibrium, while holding surface and tropospheric temperatures and state variables such as water vapor and cloud cover fixed at the unperturbed values.

Risk tolerance: While risk appetite is about the pursuit of risk, risk tolerance is a self-defined quantity of probable risk an organization can reasonably withstand (Jones and Freund 2015).

Sequestration: The uptake (i.e. the addition of a substance of concern to a reservoir) of carbon containing substances, in particular carbon dioxide (CO2), in terrestrial or marine reservoirs. Biological sequestration includes direct removal of CO2 from the atmosphere through land-use change (LUC), afforestation, reforestation, revegetation, carbon storage in landfills and practices that enhance soil carbon in agriculture (cropland management, grazing land management). In parts of the literature, but not in this report, (carbon) sequestration is used to refer to Carbon Dioxide Capture and Storage (CCS).

Stationarity: A process where the mean and variance do not change over time.

Sub-seasonal: Time scale which addresses 10-30 days where forecasting sustained high-impact weather events (i.e., heat waves, cold waves, heavy rainfall) is valuable for operational decision making.

Thermohaline circulation: Large-scale density-driven circulation in the ocean, caused by differences in temperature and salinity. In the North Atlantic the thermohaline circulation consists of warm surface water flowing northward and cold deep water flowing southward, resulting in a net poleward transport of heat. The surface water sinks in highly restricted sinking regions located in high latitudes.

Tropopause: The boundary between the troposphere and stratosphere.

Moisture Management in Other Handbook Chapters 37.12

THE TERM **moisture** encompasses the gaseous, liquid, and solid states of water and any dissolved contaminants. Examples of liquid moisture include precipitation, wind-driven rain, construction moisture, rising damp, and water from incidental pipe drippings. Precipitation wets pitched roofs, low-slope roofs, and inclined facades, whereas wind-driven rain wets the enclosure as a whole. Buildings, including the envelope, start their service life containing significant quantities of construction moisture. This is particularly true for concrete, aerated concrete, mortar, and plaster. Groundwater and rain sinks may lead to rising damp, and pipe leakage reflects bad workmanship, lack of maintenance, failing fixtures, or pipe corrosion (Hens 2016; Mumovic and Santamouris 2009; Trechsel 1994). This chapter presents data on indoor vapor release and measured indoor/outdoor vapor pressure or vapor concentration differences not included elsewhere in the *ASHRAE Handbook*, and discusses moisture sources and sinks that can reduce materials' durability, as well as the negative effects of insufficient or excessive indoor relative humidity.

Gaseous water (**vapor**) comes from outdoor humidity and from interior vapor releases. Water vapor in the air, expressed as **relative humidity**, governs hygroscopic loading of materials. High relative humidity values at surfaces favor mold growth and, if reaching 100%, can lead to surface condensation. When vapor pressure and temperature gradients in and across assemblies point in the same direction, interstitial condensation is possible.

Chapter 25 contains an in-depth analysis of heat, air, and moisture loads; Chapter 15 discusses surface condensation on windows; and Chapter 16 covers interstitial condensation caused by air leakage.

Excessive indoor moisture and humidity interferes with the use and enjoyment of buildings and may shorten their useful life over the long term. Problems affecting owners and occupants include reduced comfort, poor indoor air quality, negative health effects, damage to the building's materials and structural fasteners and wasted energy in HVAC operation. Consequently, moisture management demands attention from the architect, the builder, the mechanical system designer, and those charged with budgeting, management and maintenance of the building and its mechanical systems.

All buildings experience occasional extremes in relative humidity and moisture. Short-term occurrences of these extremes can generally be accommodated by storage in the building materials, but when moisture and humidity accumulate for extended periods in vulnerable materials, major problems can and often do occur. Moisture problems are unfortunately quite common in buildings. It is the responsibility of those in a position of authority to reasonably reduce the risks associated with excessive moisture accumulation. Successful management of moisture and humidity requires understanding the complex and dynamic relationship between the building's enclosure, its fabric, and the mechanical systems over the entire life of that building. This dynamic interaction holds the potential for either an excellent result over decades, or for frequent, disruptive, and expensive problems. Experience suggests that human behavior can overcome virtually any building technology, so owner and occupant education are important elements in the successful design and usage of a building.

The preparation of this chapter is assigned to TC 1.12, Moisture Management in Buildings.

1. EFFECTS OF HUMIDITY AND DAMPNESS

Moisture tolerance and appropriate indoor relative humidity levels must be considered requirements for a sustainable built environment: relative humidity affects comfort, indoor air quality, and health, and excessive wetness can shorten the service life of materials and assemblies. The preferred relative humidity range for human health and comfort is between 40 and 60%, although that interval is often broadened from 30 to 70%. High relative humidity degrades thermal comfort once the operative temperature passes 25 to 27°C, making the environment feel oppressive. It also facilitates release of volatile organic compounds (VOCs), especially of formaldehyde, thus degrading indoor air quality and triggering olfactory dissatisfaction. Finally, high relative humidity in specific environments (e.g., beds, on surfaces) activates dust mite reproduction and related allergy risks, and can activate mold germination and growth (ASHRAE 2012; IEA-EBC 1990a, 1990b).

Very low relative humidity activates electrostatic discharge and leads to complaints of dry mucous membranes (e.g., nose, lips, throat) and eyes, especially by people wearing contact lenses. On the other hand, some respiratory ailments can be relieved by dry environments.

Excessively low or high relative humidity creates conditions favorable to bacterial and viral infections, allergic rhinitis, and asthma. Chapter 9 gives a more in-depth analysis of the impact of humidity on thermal comfort. Chapter 10 discusses the effects of relative humidity on indoor environmental quality, Chapter 11 covers mold, and Chapter 12 discusses the relationship between relative humidity and olfactory perception. Additional information is available in Holm (2008).

Prolonged and excessive relative humidity and wetness can degrade materials physically, chemically, and biologically. Examples of physical degradation are frost damage and salt attack. Chemical degradation includes lime/gypsum reaction, carbonization of concrete, alkali/granulates reaction in concrete, and corrosion of ferrous and nonferrous metals, where moisture determines whether damage will occur in the presence of corrosive agents (e.g., sulfide, acetic acid). Wood rot by fungi and bacteria is an example of biological degradation. Very dry conditions also can damage wood, causing cracking and warping. Fluctuations between extremes of high and low relative humidity can induce cracking in hygroscopic materials.

2. ELEMENTS OF MOISTURE MANAGEMENT

Designing for moisture and humidity management includes the choice of building materials and the layering of the envelope as well as the design and component selection of the HVAC system. For information on the building envelope, refer to Chapter 15; for details on building assemblies, see Chapters 25, 26, and 27.

Licensed for single user. © 2021 ASHRAE, Inc.
Copyright © 2021, ASHRAE

The largest contributors of liquid moisture are water from wind-driven rain in building envelopes with insufficient drainage, leaks from roof or gutters, and leaks from internal plumbing. These sources must be addressed and resolved for the building envelope to succeed.

Once liquid water is addressed, the next factors to consider are vapor pressure and relative humidity. The driving forces responsible for water vapor movement within buildings and across the envelope are air pressure differences that move air and vapor together, and vapor pressure differences that activate vapor diffusion. Temperature-, wind-, and fan-induced air-pressure differentials typically overwhelm diffusion in terms of total vapor flux displaced. However, in hot, humid climates or in buildings with high indoor/outdoor vapor pressure differences, pure diffusion may nevertheless cause problems.

Chapters 16 and 20 contain information on air movement in buildings. Chapter 13 gives information on intrazone airflow, multizone network airflow, and contaminant transport, included vapor; and Chapter 24 discusses airflow around buildings. ANSI/ASHRAE *Standard* 160-2009 provides criteria to evaluate the transient hygrothermal performance of envelopes. This analysis may be used to evaluate moisture tolerance in cases where, besides vapor, liquid water is a primary factor.

3. ENVELOPE AND HVAC INTERACTIONS

As shown by Figure 1, heat, air, and moisture move continuously throughout a building, driven by differences in temperature, vapor pressure, and air pressure between the indoor and outdoor environment and by similar differences between adjacent indoor zones. Construction moisture contributes to the initial wetness of the whole building fabric, including the envelope. Over time, envelope assemblies exposed to rain and snow may become moist by seeping rain and melting snow or by capillary suction **(rising damp)** from moist below-grade earth, which may dampen walls just above grade. Leaking and dripping interior pipes can also be responsible for excessive wetness.

The opaque and transparent portions of the building envelope must be designed so that their thermal transmittance approaches the energy related economic optimum. Together with the overall building fabric, the envelope should allow passive solar control, while all

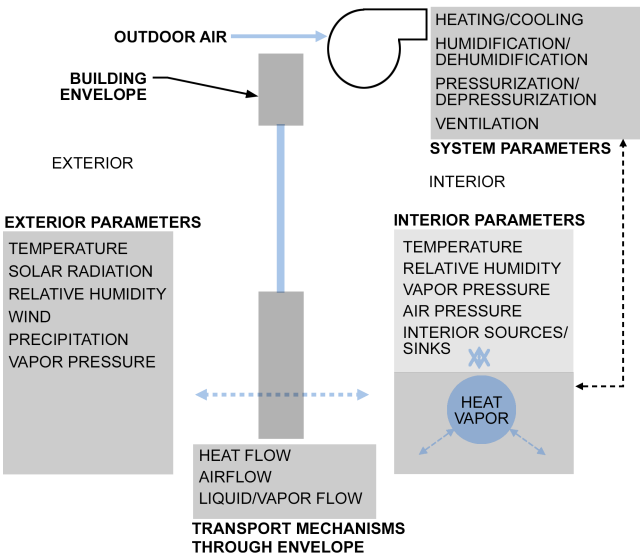

Fig. 1 Dynamic Interaction Between Air, Moisture, and Materials in HVAC Systems and Building Envelope

assemblies proposed must prevent rain from wetting layers that must stay dry. The building details should withhold rainwater runoff and prevent sinking rainwater from wetting basements and floors on grade. Correct protective measures must exclude rising damp and promote effective construction moisture drying; water vapor moving across the envelope assemblies should not result in unacceptable interstitial moisture accumulation. Detailing and workmanship must minimize air leakage across the envelope as well as wind washing, indoor air washing, and air looping within envelope assemblies. Correct design, workmanship, and maintenance should prevent plumbing leakages or sweating of pipes running in or across walls and floors.

The HVAC system must provide a thermally comfortable and healthy indoor environment. Ventilation is necessary for delivering fresh air to building occupants. To maintain a set-point temperature when heat losses by transmission, infiltration, and ventilation exceed solar gains through the transparent and opaque envelope parts and internal gains by lighting, appliances and occupancy, heating is required. If, instead, the gains exceed the losses, cooling is needed. In both cases, the temperature difference with outdoors creates a thermal stack effect, which together with wind and fan operation maintains air pressure differentials with the exterior.

In heating mode, the indoor vapor concentration is typically left free floating, fluctuating with the vapor in the ventilation and infiltration air and the vapor released indoors. The net vapor concentration and the air temperature maintained by the HVAC system then determine the relative humidity indoors. Only when the ventilation and infiltrating air is too dry or too humid, when the vapor release indoors is very high, or when the building's function requires relative humidity control, must the HVAC system actively intervene to control humidity by removing water vapor from or adding water vapor to the indoor air (dehumidification and humidification). The energy required to humidify or dehumidify is called the **latent heat load**. In cooling mode, the latent load derives from the supply air temperature required for cooling, the dew-point temperature of the outdoor air, and the vapor released indoors. Condensation on the coil removes some portion of the moisture in the incoming ventilation air.

4. INDOOR WETTING AND DRYING

HVAC design or a durability assessment of the envelope and the whole building during design requires knowledge of the expected indoor humidity conditions. This is essential for making the right decisions to prevent mold, surface condensation, problematic interstitial condensation, and reduced drying.

The function of a building and the conditions outdoors dictate whether the indoor relative humidity needs control. The vapor balance, which considers the various mechanisms involved in vapor release, vapor removal, and vapor storage, is fundamental for this decision. One of the unknowns in this balance is the vapor release related to building use. A first approach consists of quantifying these releases directly. A second approach to get information starts from extended indoor/outdoor climate measurements in large sets of buildings to deduce a statistically relevant indoor-to-outdoor time-averaged difference in vapor pressure or vapor concentration in relation to the outdoor air temperature. Both methods are discussed in the following.

Understanding Vapor Balance

The air humidity indoors is assumed to be free floating. Five vapor fluxes then contribute to maintaining the equilibrium in a room:

- Vapor carried and supplied by infiltrating outdoor air and ventilation
- Vapor removed by exfiltrating indoor air and exhaust air
- Vapor released by occupants and their activities, by plants, water surfaces, and drying fabric parts

Licensed for single user. © 2021 ASHRAE, Inc.

- Vapor adsorbed and desorbed by all hygroscopic surfaces present
- Vapor condensing on indoor surfaces that are colder than the dew-point temperature indoors or evaporating from indoor surfaces wetted by surface condensation

These five fluxes load and unload the room air with vapor. There is even a sixth flux: vapor inflow and outflow by diffusion through the envelope. Its magnitude, however, is insignificant compared to the five fluxes mentioned, hence ignoring it does not introduce any significant error.

Assuming ideal air mixing, the balance per room is expressed by

$$\sum G_{a,in} x_{v,in} + \sum G_{a,out} x_{v,i} + \sum_{j=1}^{n} \beta_j A_j (p_{sat,A_j} \phi_{A_j} - p_i) + \sum_{k=1}^{m} \beta_k A_k (p_{sat,A_k} - p_i) + G_{v,P} = V \frac{dx_{v,i}}{dt} \quad (1)$$

where

$G_{a,in}$ = all airflows entering room, including infiltration from outdoors, ventilation supply air, and infiltration from adjacent rooms, kg/s
$x_{v,in}$ = ratio of water vapor to dry air in entering air, kg/kg
$G_{a,out}$ = all airflows leaving room, including exfiltration to outdoors, exhaust air, and exfiltration to adjacent rooms, kg/s
$x_{v,i}$ = ratio of water vapor to dry air in room, kg/kg
β_j = surface film coefficient for diffusion at each hygroscopic surface, kg/(m²·s·Pa)
A_j = area of each hygroscopic surface in room, m²
p_i = water vapor pressure in room, Pa
$p_{sat,Aj}$ = vapor saturation pressure at different hygroscopic surfaces in room (fabric, furniture, and furnishings), Pa
$\phi_{sat,Aj}$ = relative humidity at different hygroscopic surfaces (fabric, furniture, and furnishings) in room on a scale from 0 to 1
β_k = surface film coefficient for diffusion at all room surfaces where vapor condenses or evaporates, kg/(m²·s·Pa)
A_j = area of all room surfaces experiencing surface condensation or surface condensate drying, m²
$p_{sat,Aj}$ = vapor saturation pressure for room's various condensing and evaporating surfaces, Pa
$G_{v,P}$ = vapor release in room, kg/s
V = air volume of room, m³
t = time, s

Solving Equation (1) requires knowledge of all in- and exfiltrating airflows between the room and all adjacent rooms and between the room and the outdoors, the ventilation supply airflow, exhaust airflow, water vapor ratio transported by all four airflows, surface temperatures and vapor balances at all hygroscopic surfaces, surface temperatures at all condensing and drying surfaces, and the surface film coefficients for diffusion at each of these surfaces (Hens 2012). Calculating requires numerical methods (preferably with dedicated software) to account for the transient nature of the variables involved (Woloszyn and Rode 2008).

In reality, because of stack effects, supply air jets, and convective plumes around people, the air in a room is never fully mixed, and vapor pressure gradients exist inside every room. Wetter, warmer air is also lighter and creates a positive temperature and humidity gradient along a room's height, even in stagnant conditions. Despite these internal gradients, whose quantification requires computational fluid dynamics (CFD) calculations, further discussion is based on the fully mixed assumption.

When considering steady-state conditions where the room air maintains an average humidity that does not change with time (e.g., because sorption/desorption by the hygroscopic surfaces no longer intervenes and all airflows and vapor releases are time averaged), in the absence of surface condensation and surface drying, the humidity balance per room simplifies to

$$\sum G_{a,in} x_{v,in} + \sum G_{a,out} x_{v,i} + G_{v,P} = 0 \quad (2)$$

If the only incoming airflow is from the outdoors (e.g., infiltration, natural ventilation, air-side economizer applications), equality between supply and exhaust yields the mean indoor relative humidity:

$$\phi = \frac{1}{p_{sat,i}} \left[\phi_o p_{sat,o} + \frac{R(273.15 + \theta_i) G_{v,P}}{\dot{V}_a} \right] \quad (3)$$

where

ϕ_i = indoor relative humidity on scale from 0 to 1
$p_{sat,i}$ = vapor saturation pressure for indoor temperature, Pa
ϕ_o = outdoor relative humidity on scale from 0 to 1
$p_{sat,o}$ = vapor saturation pressure for outdoor temperature, Pa
R = gas constant for water vapor, equal to 462 (Pa·m³)/(kg·K)
θ_i = indoor temperature, °C
$G_{v,P}$ = average indoor vapor release, kg/h
$\dot{V}_a$ = outdoor air ventilation or/and infiltration flow, m³/h

Relative humidity over longer periods of time thus depends on mean outdoor temperature (through $p_{sat,e}$), mean outdoor relative humidity, mean indoor air temperature (through $p_{sat,i}$), mean indoor vapor release, and mean outdoor air ventilation and/or infiltration flows.

In cold and temperate climates, the outdoor air ventilation required by building standards easily dilutes the vapor released in residences, offices, and schools. In temperate climates, heating tends to keep relative humidity levels below the upper acceptability threshold. In very cold climates, ambient temperature and outdoor relative humidity may be such that normal ventilation rates cannot raise the indoor relative humidity above 15 to 20% at room temperature. Humidification may then become necessary. In hot, humid climates, outdoor temperature and relative humidity can be so high that the combined action of ventilation, cooling, and vapor release raises the indoor relative humidity above the upper acceptability threshold. Supplemental air dehumidification then is required.

Where outdoor air infiltrates into the room and the ventilation system delivers supply air at a fixed condition, the mean relative humidity indoors becomes

$$\phi = \frac{1}{p_{sat,i}} \left[\frac{\dot{V}_{a,inf} p_{sat,o} \phi_o + \dot{V}_{a,s} p_{sat,s} \phi_s}{\dot{V}_{a,inf} + \dot{V}_{a,s}} + \frac{R(273.15 + \theta_i) G_{v,P}}{\dot{V}_{a,inf} + \dot{V}_{a,s}} \right] \quad (4)$$

where

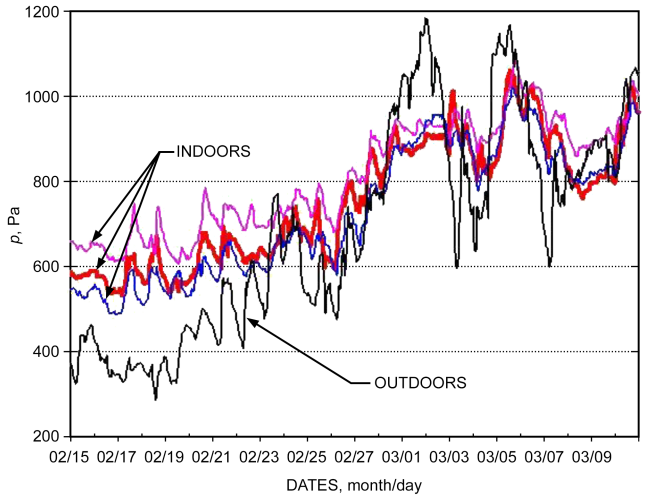
ϕ_o = outdoor relative humidity on scale from 0 to 1
$p_{sat,o}$ = vapor saturation pressure for outdoor temperature, Pa
ϕ_s = relative humidity of supply air on scale from 0 to 1
$p_{sat,s}$ = vapor saturation pressure for supply air temperature, Pa
$\dot{V}_{a,inf}$ = infiltrating volumetric outdoor airflow, m³/h
$\dot{V}_{a,s}$ = volumetric supply airflow, m³/h

Hygric Buffering

In hygric buffering, vapor from the air is adsorbed into hygroscopic materials when the relative humidity rises, and released back into the air when the relative humidity lowers. On shorter time scales, hygric buffering by various elements such as indoor air and the building fabric (e.g., envelope, furniture, furnishings) dampens and shifts fluctuations in relative humidity and consequently in indoor vapor pressure compared to the fluctuations of the exterior vapor pressure and internal vapor release.

Figure 2 compares measured indoor vapor pressures in an office building with the exterior vapor pressure over the course of a winter month when exterior conditions changed from cold and dry to warmer

Licensed for single user. © 2021 ASHRAE, Inc.



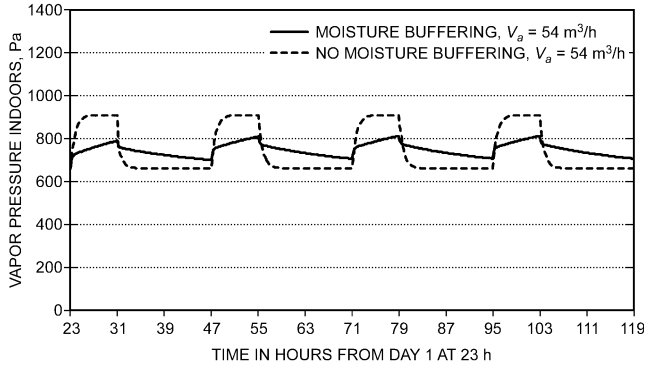


Fig. 2 Measured Water Vapor Pressure Outdoors and Indoors for Office Building

Room is 16 m² with air volume of 40 m³. Walls and ceiling finished with papered gypsum plaster, with (solid curve) and without (dashed curve) its moisture-buffering effects taken into account.

Fig. 3 Daily Vapor Pressure in Two-Person Bedroom

and more humid (Hens 2009a). Indoor vapor pressure remained higher than the outdoors during the cold, dry spell but dropped lower than outdoors during the warmer and more humid spells. Figure 3 shows the calculated buffering effect on the daily indoor vapor pressure in a well-ventilated two-person bedroom during winter (Hens 2012a). The effects of hygric buffering in keeping the daily changes in vapor pressure much lower than if only the air acted as buffering volume are obvious.

Antretter et al. (2012) performed a series of buffering experiments in a test room, simulating 4 to 6 day periods of summer and winter conditions. For the summer simulation, conditions were kept constant at 20°C, 90% rh, and 1 air change per hour (ach) for 1 to 3 days, then altered to an air change rate of zero and brought up to 35°C in 2 h. These conditions were held for 10 h, after which the temperature was returned to 20°C in 2 h and held there for the next 3 days. For the winter simulation, conditions were kept constant at 23°C, 50% rh, and 1 ach for 1 to 3 days, followed by 3 days with two vapor release peaks and a drop in the air change rate from 1 to 0.5 ach. The reference experiment was initially done without moisture buffering, and then repeated with 27 0.3 × 0.3 m sorptive tiles in the room. Figure 4 shows how the relative humidity changed the day after the initializing period. The effect of buffering is evident.

Hygroscopic buffering can even induce dampening and phase shifting on an annual basis in buildings with massive construction,

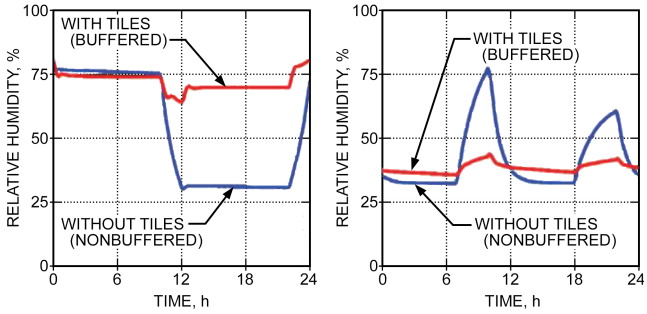

Fig. 4 Comparison of Daytime Relative Humidity for Summer and Winter Case
(Antretter et al. 2012)

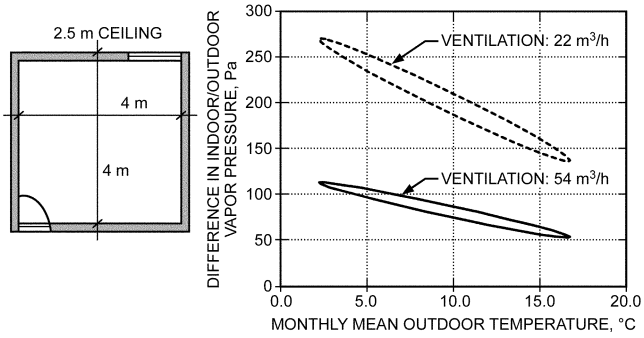

Fig. 5 Annual Monthly Averaged Indoor/Outdoor Vapor Pressure Difference in Bedroom of Figure 3

as shown by Figure 5 for the same bedroom as in Figure 3 (Hens 2012a). For the same vapor release indoors and constant ventilation rate, the monthly mean indoor vapor pressures form an inclined ellipse, with the highest value in winter, lowest in summer, and values lower in springtime than in autumn.

5. VAPOR RELEASE RELATED TO BUILDING USE

Water vapor indoors comes from several sources: building occupants and their activities (e.g., cleaning, cooking, showering, bathing), pets, plants, water surfaces, drying of wet fabric parts, etc. Releases can be divided into those dependent on indoor temperature and relative humidity, such as free water surfaces and wet fabrics, and those generally independent of these factors, such as human activities and plants (TenWolde and Pilon 2007). Accounting for these two types of sources, Equation (3) expands into

$$\phi_i = \frac{1}{p_{sat,i}} \times \frac{[\phi_o p_{sat,o} + R(273.15 + \theta_i)(G_{vp} + \beta A_w p_{sat,w})/V_a]}{1 + R(273.15 + \theta_i)\beta A_w / V_a} \quad (5)$$

where A_w is the free water surface, in m².

Solving Equations (3) and (4) presumes knowledge of the magnitudes of the water vapor sources.

Residential Buildings

Estimating moisture loads requires knowledge of occupancy patterns and releases per individual, activity, plant, and water surface present. In most cases, the real occupancy is unknown, and the sources are even more difficult to quantify. Some activities in the same classification differ in the amount of vapor released (e.g.,

cooking, which varies with the type of meals prepared). Literature sources only give global average numbers and should therefore be used with care and understanding of the implicit assumptions. Tables 1 to 5 list example amounts by type (IEA-ECB 1990; Kumaran and Sanders 2008; Sanders 1996; TenWolde and Walker 2001).

The means in Table 6 yield, as least-square regressions,

$$G_{v,P} = 0.34 + 3.88n \ (r^2 = 0.999) \text{ in kg/day} \quad (6)$$

The individual data, however, produce a different relationship with considerably more scatter:

$$G_{v,P} = 3.23 + 2.82n \ (r^2 = 0.999) \text{ in kg/day} \quad (7)$$

In both equations, n is the number of family members weighted by the ratio between the hours each is at home and 24 h a day. For example, if four people occupy the home for 16 h daily, n is

$$n = 4 \times \left(\frac{16}{24}\right) = 2.7$$

Equation (7) indicates that each person who is at home 24 h/day adds 2.82 kg of water vapor to the indoor ambient. Measurements in some German apartments, however, suggested that this release rate is too high: for a family of three, the rates documented ranged from 5.6 to 7.8 kg per day (Hartmann et al. 2001), giving a value between 0.8 and 2.48 kg per person per day. Data from Estonia suggest a person present 24 h/day adds on average 1 kg to the vapor released (Kumaran and Sanders 2008).

Table 7 provides some country-related statistical information about the vapor release expected in different types of residential buildings.

Natatoriums

Evaporation from the pool surface, wet swimmers, and the wet floor around the pool are the main sources of water vapor. The evaporation rate is calculated based on the pool surface, multiplied by a factor that accounts for the average number of pool users and the wet floor around the pool:

$$G_{v,P} = f \beta A_{pool} (p_{sat,\,pool} - p_i) \quad (8)$$

where

$G_{v,P}$ = evaporation rate, kg/s
β = surface film coefficient for diffusion at water surface in pool, kg/(m^2·s·Pa)
f = factor that accounts for average number of pool users and wet floor around pool
A_{pool} = water surface area, m^2
$p_{sat,\,pool}$ = vapor saturation pressure at pool's water temperature, Pa

In cases where the airflow comes from outdoors, Equation (9) can be combined with Equation (3) to yield the mean vapor pressure in a natatorium:

$$p_i = \frac{\phi_o p_{sat,o} + p_{sat,pool}[R(273.15 + \theta_i)\beta f A_{pool}]/V_a}{1 + [R(273.15 + \theta_i)\beta f A_{pool}]/V_a} \quad (9)$$

Measurement of the water surface, water temperature, air temperature, relative humidity, ventilation supply flow, and number of users in a university and a recreation natatorium allowed estimating a surface film coefficient for diffusion β, with inclusion of the factor f (Table 8). For the university natatorium, the table includes all measured evaporation rates in g/(m^2·h).

Using the data from the university pool in Table 8, the unknown factor f could be derived as a function of the number of pool users (Hens 2009b):

$$f = 1 + 8.46n \ (r^2 = 0.95) \quad (10)$$

where n is the number of users per square metre of pool surface.

For zero users, f is 1. The least-square line is depicted in Figure 6.

For example, given a water surface of 50 × 20 m, a water temperature of 28°C, an air temperature of 30°C, an indoor relative humidity of 60%, and 100 pool users, evaporation amounts to 80 kg/h.

6. INDOOR/OUTDOOR VAPOR PRESSURE DIFFERENCE ANALYSIS

Measuring vapor release rates directly is a difficult and time-consuming task. The typical alternative is to monitor the indoor temperature and relative humidity and then compare the related mean indoor vapor pressure to the mean value outdoors. Therefore, most experiments looking to quantify air humidity in buildings use the **average indoor/outdoor vapor pressure difference** Δp_{io} or **average indoor/outdoor vapor concentration difference** $\Delta\rho_{io}$, represented by the second term in Equation (3) (i.e., the ratio between the average water vapor release and the average infiltration and ventilation flow):

$$\Delta p_{io} = \frac{R(273.15 + \theta_i)G_{v,p}}{\dot{V}_a} \text{ in Pa} \quad (11a)$$

or

$$\Delta\rho_{io} = \frac{G_{v,p}}{\dot{V}_a} \text{ in g/m}^3 \quad (11b)$$

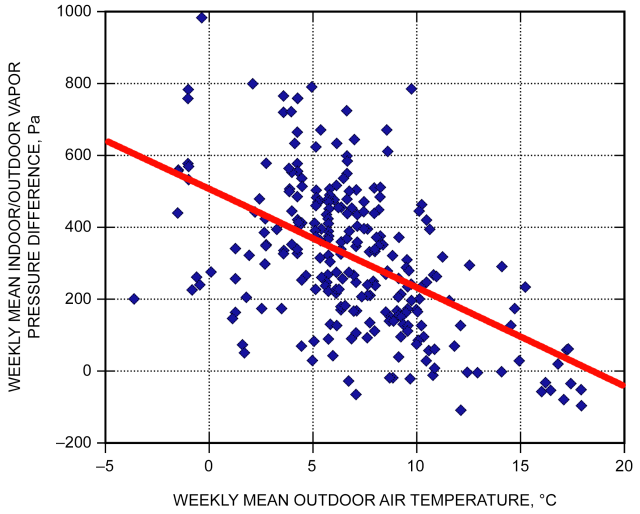

Fig. 7 Daytime Rooms in Dwellings

That difference over a given time span is mostly linked to the average air temperature outdoors over the same time span.

Residential Buildings

In North America and Europe, there have been many monitoring programs in residential buildings that gathered data on the indoor/outdoor vapor pressure and vapor concentration difference. The least-square linear relationships found between these data, averaged over a given time span, and the outdoor air temperature averaged over the same time span typically show a decreasing trend at higher temperatures. Figure 7 shows such a measured relationship for a region where massive construction prevails and homes tend to be naturally ventilated (Hens 2016).

There are two reasons for the decrease shown in Figure 7: (1) windows are more frequently opened in warmer weather, resulting in more outdoor air ventilation and thus lower indoor/outdoor vapor pressures and concentration differences at higher outdoor air temperatures; and (2) the massive building fabric that absorbs and releases significant amounts of vapor and consequently dampens and shifts the indoor vapor pressure compared to the outdoors even on an seasonal basis.

Ridley et al. (2008) took long-term measurements in 1065 U.K. living rooms and 916 U.K. bedrooms. The least-square regressions, based on half-hour averages, are shown in Figures 8 and 9. They are given by

Living rooms:

$$\Delta p_{ie} = 400 - 19\,\bar{\theta}_e \text{ in Pa} \quad (12)$$

Bedrooms:

$$\Delta p_{ie} = 425 - 23.6\,\bar{\theta}_e \text{ in Pa} \quad (13)$$

Figure 10 and Table 9 are based on measurements in 101 dwellings in Finland and Estonia (Kalamees et al. 2006). The data gained were approximated by three distinct linear segments with the running weekly average indoor/outdoor vapor pressure differences constant below5°C and above 15°C outdoors and varying linearly in

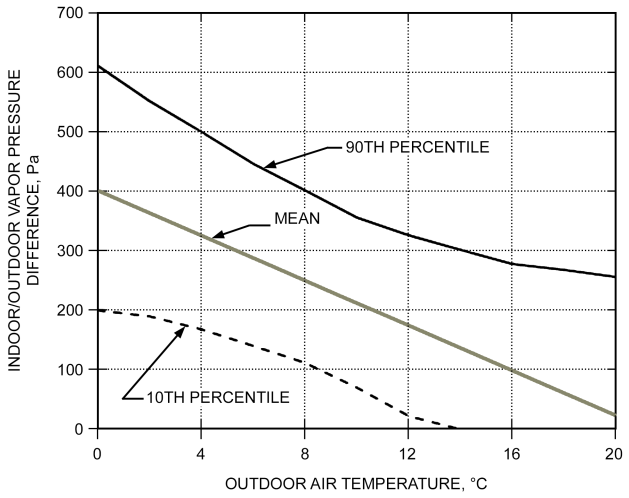

Fig. 8 Indoor/Outdoor Vapor Pressure Difference in 1065 U.K. Living Rooms

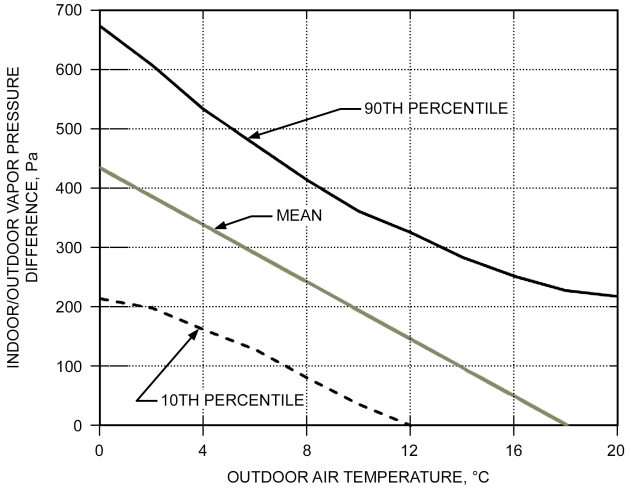

Fig. 9 Indoor/Outdoor Vapor Pressure Difference in 916 U.K. Bedrooms

Table 9 Finland and Estonia, Indoor Climate, Boundaries (Weekly Means)

	Indoor/Outdoor Vapor Pressure Difference, Pa		
Humidity Load	$\bar{\theta}_{e,w} < 5°C$	$5°C \le \bar{\theta}_{e,w} \le 15°C$	$\bar{\theta}_{e,w} > 15°C$
Low	540	$0.388 - 0.00556\,\bar{\theta}_{e,w}$ $540 - 34\,\bar{\theta}_{e,w}$	200
Average	680	$0.473 - 0.00667\,\bar{\theta}_{e,w}$ $680 - 41\,\bar{\theta}_{e,w}$	270
High	810	$0.559 - 0.00778\,\bar{\theta}_{e,w}$ $810 - 47\,\bar{\theta}_{e,w}$	340

between. A distinction was also made between high, average, and low vapor load.

The data collected in northern Canada (Kumaran and Sanders 2008) are represented by dots in Figure 10. The average indoor/outdoor vapor pressure the dot at top left represents a four-day period where the average outdoor temperature was –18°C and is substantially higher than the Finnish and Estonian high humidity results,

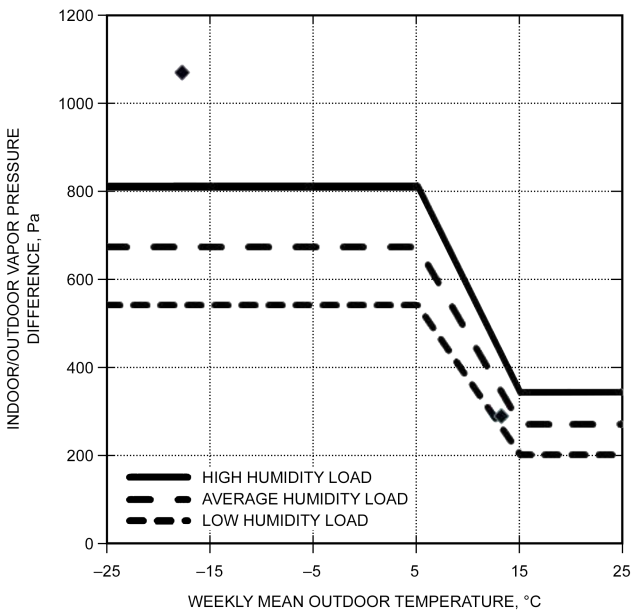

Fig. 10 Water Vapor Pressure Excess in Relation to the Running Weekly Mean Temperature for Northern Europe and Canada

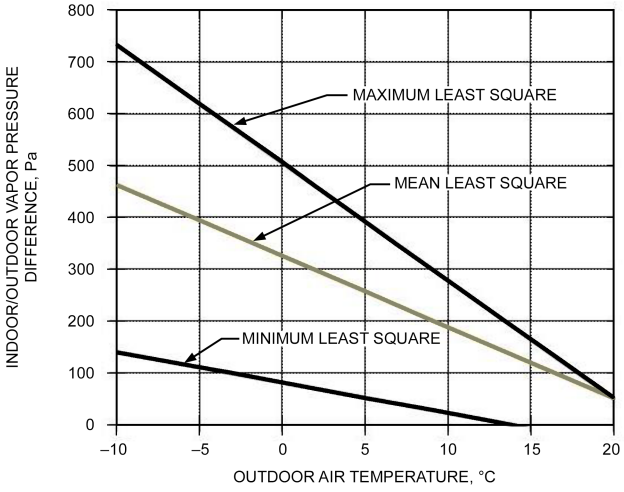

Fig. 11 Indoor/Outdoor Vapor Pressure Differences for 10 German Living Rooms

apparently because a boil-water safety advisory led to an extremely high vapor release. The other dot at 13°C outdoor temperature is close to the Finnish and Estonian low-humidity curve, even though the number of household members was higher than typical for southern Canada. The dwellings monitored were measured to have air change rates up to 12 ach at 75 Pa.

Measurements in the living rooms of 10 German homes are shown in Figure 11. The main variable seems to be the number of household members and their living habits, including window operation (Antretter et al. 2010).

Comparing the mean of the German averages with those from the U.K. in Figures 8 and 9 gives smaller differences at low outdoor temperatures, and higher differences at higher outdoor temperatures:

$$\Delta\bar{p}_{ie} = 328 - 13.7\,\bar{\theta}_e \text{ in Pa} \quad (14)$$

Licensed for single user. © 2021 ASHRAE, Inc.

Temperature and relative humidity data collected in 60 homes, equally spread over three climate zones in the United States (Pacific northwest, a cold location in the northeast, and a hot and humid location in the southeast) gave the values plotted in Figure 12 as the average relation between the moving monthly mean outdoor temperature and the moving monthly mean indoor/outdoor vapor pressure difference (Arena et al. 2010).

Figure 12 clearly shows the dehumidifying effect of air conditioning. The least-square regression line for a running monthly mean outdoor temperature below 19.5°C equals

$$\Delta \bar{p}_{ie} = 397 - 16.3\,\bar{\theta}_e \quad (r^2 = 0.86) \tag{15}$$

Above 19.5°C, the line becomes

$$\Delta \bar{p}_{ie} = 2807 - 140\,\bar{\theta}_e \quad (r^2 = 0.92) \tag{16}$$

Indoor/outdoor vapor concentration difference measurements in 10 homes in Madison, WI, and 10 homes in Knoxville, TN, over a one-year period gave as monthly means the values shown in Figure 13 (Antretter et al. 2010).

The data are consistent with what Figure 12 shows: vapor pressure deficits only occur during the summer months in the Madison climate, and between April and November in the warmer, more humid Knoxville climate. Both situations are the result of dehumidification by air conditioning.

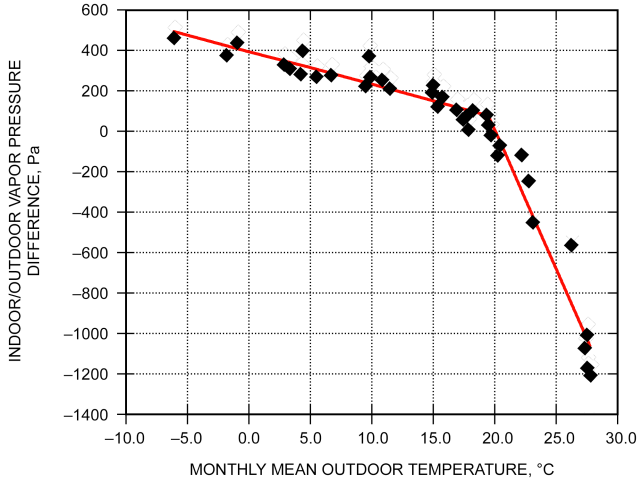

Fig. 12 Monthly Mean Indoor/Outdoor Vapor Pressure Difference in Relation to Monthly Mean Outdoor Air Temperature in Three U.S. Climate Zones

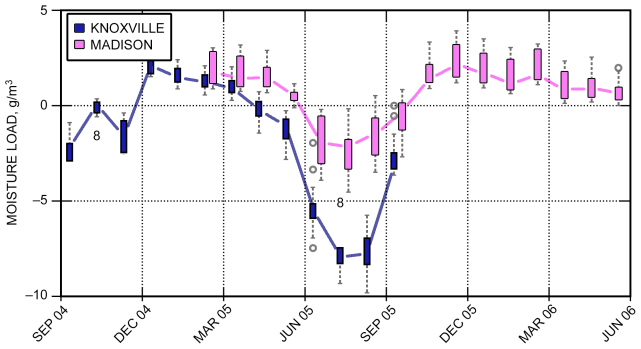

Fig. 13 Measured Monthly Mean Indoor/Outdoor Vapor Concentration Difference in 10 Homes in Madison, WI, and 10 Homes in Knoxville, TN
(Antretter et al. 2010)

Measurements taken in 71 homes in Rhode Island are shown in Figure 14, giving the distribution of the measured indoor/outdoor vapor pressure difference at 0°C outdoors (Francisco and Rose 2010).

The mean was 396 Pa, close to what Equation (15) suggests, whereas the 95th percentile value equaled 772 Pa. This is higher than the data measured (Hens 2016) in the temperate climate of northwestern Europe, where for larger homes the 95th percentile on a weekly basis was

$$\Delta \bar{p}_{ie} = 540 - 29\,\bar{\theta}_e \quad \text{(Pa)} \tag{17}$$

whereas for small homes the relation was

$$\Delta \bar{p}_{ie} = 670 - 29\,\bar{\theta}_e \quad \text{(Pa)} \tag{18}$$

To minimize risk, the 95th percentile is often used for design purposes.

These results are based primarily on homes using natural ventilation. Many codes in the United States require homes to add mechanical ventilation to compensate for tighter envelopes. This significant difference must be addressed in evaluating residences with mechanical ventilation.

Measurements in 30 homes by Francisco et al. (2009) found that unvented gas fireplaces added on average about 100 Pa to the indoor/outdoor vapor pressure difference.

Natatoriums

Vapor pressure difference measurements in natatoriums are few; however, studies have been conducted in some countries. Figure 15 gives weekly mean indoor/outdoor vapor pressure differences in relation to the weekly mean outdoor air temperature, measured in 20 natatoriums in a temperate region (Hens 2016).

There is a considerable amount of scatter. Least-square regressions for the mean and 95th percentile are

Mean

$$\Delta \bar{p}_{ie} = 1228 - 27.7\,\bar{\theta}_{e,w} \quad (r^2 = 0.13) \tag{19}$$

95th percentile

$$\Delta \bar{p}_{ie} = 1841 - 27.7\,\bar{\theta}_{e,w} \quad (r^2 = 0.13) \tag{20}$$

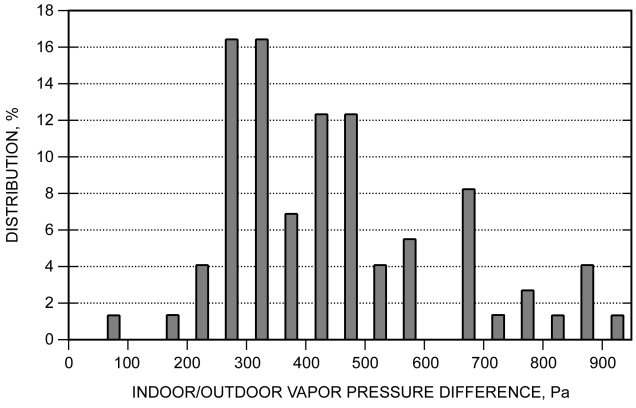

Fig. 14 Indoor/Outdoor Vapor Pressure Difference with Intersect at 0°C for 71 Rhode Island Homes

Licensed for single user. © 2021 ASHRAE, Inc.

The data clearly show that, although not highly correlated with the outdoor temperature, the vapor pressure differences in natatoriums are consistently high. These buildings therefore require specific measures to prevent moisture accumulation in the envelope, which can lead to degradation (Figure 16).

Student Residences and Schools

The few measuring campaigns undertaken in student residences and schools in a temperate-climate region gave a very diffuse picture, with a large spread in weekly mean indoor/outdoor vapor pressure differences; see Figure 17 (Hens 2005) and Table 10 (Hens et al. 2007).

7. AVOIDING MOISTURE PROBLEMS

Avoiding mold, surface condensation, and interstitial condensation in cold and temperate climates requires the following measures:

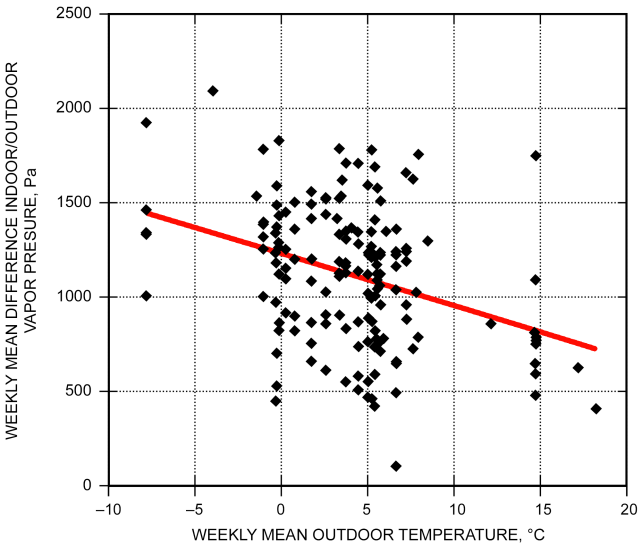

Fig. 15 Weekly Mean Indoor/Outdoor Vapor Pressure Differences for 20 Natatoriums (Measured Data and Least-Square Straight Line)

Fig. 16 Natatoriums: (A) Low-Sloped Roof Damaged by Convection-Induced Interstitial Condensation; (B) Interstitial Condensation in Low-Sloped Roof Polyurethane Foam Insulation; (C) Timber Beam Collapse; (D) Abundant Surface Condensation on Window and Lintel

- Building envelopes must be insulated such that the risk of surface mold and surface condensation at room temperature and typical levels of relative humidity is as close to zero as possible. Insulation requirements imposed by current building codes for energy efficiency are typically much higher than those needed to address risk of condensation.
- Avoid structural thermal bridges. No point on the indoor surface of an opaque portion of the envelope should be colder than the indoor surface of the glazed portion
- Minimize infiltration and exfiltration by making the envelope as airtight as possible.
- Avoid air gaps in envelope construction that would lead to wind washing in and along the inner face, and indoor air washing along the outer face of the thermal insulation.
- For low-mass construction in heating-dominated climates, if necessary, mount a continuous vapor retarding layer at the inner side of the insulation. In hot, humid climates, install the vapor control on the exterior or warm side of the insulation or building envelope.
- Vapor control layers should be used with caution in stone and masonry construction. Take measures to avoid problems with solar-driven vapor flow when applying vapor retarders on the inner side of envelopes that have a rain-buffering outer finish, such as a brick veneer [see Derome and Saneinejad (2009)].
- Never sandwich layers between vaportight materials on both sides. This is especially detrimental when thermal insulation is one of the layers and the others contain construction moisture.

Table 10 Indoor Air Temperature and Indoor/Outdoor Vapor Pressure Difference: Means and Extremes Measured in Five Temperate-Climate Schools

	Temperature, °C			Indoor/Outdoor Vapor Pressure Difference, Pa		
School	Mean	Min	Max	Mean	Min	Max

HVAC Systems

The mechanical system can affect the air pressure differences among building zones, and between building zones and the outdoors. HVAC operation influences the indoor relative humidity and, consequently, indoor/outdoor vapor pressure differences. To minimize humidity concerns,

- Insulate chilled-water pipes and cool-air ducts to minimize heat gain. The insulation must have a moisture resistant vapor-control layer on the outer surface and be thick enough to prevent surface condensation. Warm-water pipes and warm-air ducts require insulation to minimize heat losses. For more details, see Chapter 23.
- Natural or mechanical ventilation in temperate climates should keep the indoor relative humidity within the 30 to 70% range.
- HVAC systems in hot and humid climates should ventilate the building while cooling and dehumidifying the ventilation air. The building should also be positively pressurized. In very cold climates, HVAC systems should ventilate and warm the building while humidifying the air and putting the building under negative pressure.

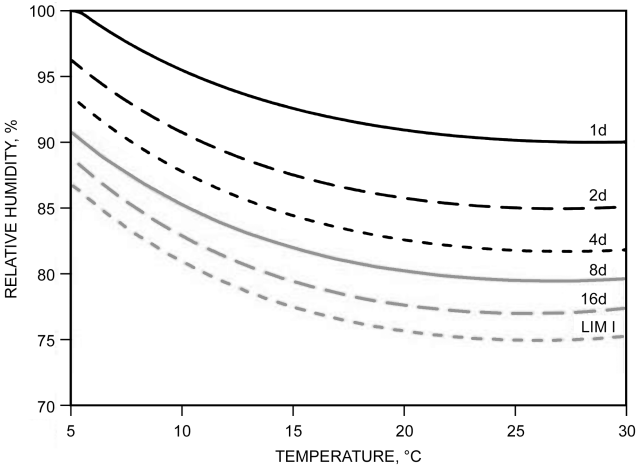
Ground Pipes

In temperate climates, ground pipes (ventilation air ducts buried in the soil near the building) are sometimes used to moderate the condition of incoming ventilation air. Rain and groundwater must be prevented from entering these pipes: water penetration turns the pipes into air humidifiers, with very negative consequences for the indoor air quality. In dry pipes, relative humidity during the warm season should not exceed the mold threshold: too high a relative humidity in the pipes can load the supply air with mold spores, which then germinate in the supply filter. These risks are high enough that ground pipes are not recommended as a safe choice (Hens 2012b).

Building Fabric

If there is no watertight layer or capillary break inserted above grade, stone-based building fabrics may suffer from rising damp and salt transport. Building parts, wetted by rising damp, act as permanent moisture sources affecting indoor vapor release and the indoor/outdoor vapor pressure difference.

Building Envelope



Even when raintightness is guaranteed, excessive indoor vapor pressures can induce mold and condensation on interior surfaces and favor interstitial condensation in assemblies. Chapters 25 and 27 deal in more detail with moisture transport in the building envelope.

Mold Growth. Mold growth begins on interior opaque surfaces where the surface temperature and relative humidity pass the **mold threshold** for a long enough period of time. For example, if a material has absorbed an amount of water from a leak, drying may temporarily sustain a surface relative humidity high enough to be conductive for mold. The IEA Annex 14 reports (IEA-EBC 1990a, 1990b) contain two design formulas for estimating mold risk. The one calculates the four-week threshold, above which the likelihood that mold will develop is close to 100%. The other evaluates the surface relative humidity needed for mold development at shorter time intervals. Combining the two yields

$$\phi_{crit} \geq \min\{100;(0.033\theta_{si}^2 - 1.5\theta_{si} + 96)[1.24 - 0.072\ln(T)]\} \quad (21)$$

where

ϕ_{crit} = relative humidity at surface, on scale from 0 to 100

Class I substrates are biologically recyclable building materials: wallpaper, plasterboard, permanent elastic joint materials, and other biodegradable materials.

Fig. 18 Sedlbauer's Isopleth System for Class I Substrates: Time Until Germination
(Sedlbauer 2001)

θ_{si} = indoor surface temperature, °C ($5°C \leq \theta_{si} \leq 25°C$)
T = time span, days

The threshold for a one-day period touches 99%.

Since completion of Annex 14, two more comprehensive models have been published: Sedlbauer (2001) (Figure 18), and Viitanen and Ojanen (2007). More recent work, however, confirms that predictions with any model give varying results for growth probability and mold density (Vereecken and Roels 2012).

Surface Condensation. Each time the indoor surface temperature somewhere on the envelope drops below the dew point of the indoor air, condensate forms. Glazed surfaces are especially prone to surface condensation. Hygroscopic materials (e.g., wood, masonry, gypsum, some plasters) may buffer the local surface wetness, preventing visible condensate but increasing the moisture content in the material. When short periods of condensation or high humidity alternate with periods of drying, there tend to be no negative consequences. Long-lasting surface condensation or long periods of high humidity, however, degrade timber and other materials, and condensate deposited on aluminum frames may wet the window reveals. Thermal bridges can experience prolonged periods of condensation that cause indoor-side finish damage, such as wallpaper glue giving away.

Interstitial Condensation. Water vapor condensation within envelope parts is called **interstitial condensation**, and is caused by temperature and vapor pressure gradients pointing in the same direction. The driving forces are diffusion driven by vapor pressure differences, moist air leakage (in- or exfiltration), or absorption of wind-driven rain. In wood and wood-based materials, interstitial condensation may lift the surface relative humidity above the mold threshold and, worse, the moisture content above the rot threshold. When the relative humidity adjacent to nonporous, nonabsorbing, or capillary wet layers in an assembly becomes 100%, condensation with droplet formation occurs, followed by runoff and sometimes dripping, which is especially annoying for the occupants.

8. CLIMATE-SPECIFIC MOISTURE MANAGEMENT

Temperate and Mixed Climates

In temperate and mixed climates, neither humidification nor dehumidification is explicitly required except when necessary for

Licensed for single user. © 2021 ASHRAE, Inc.

functional reasons, such as in museums and operating rooms. Some depressurization during winter is advisable to minimize interstitial condensation risk, such as using demand-controlled exhaust ventilation or balanced ventilation with heat recovery and a correctly chosen pressure balance between supply and exhaust. The envelope must be so airtight that depressurization will not result in ventilation airflow beyond that needed for health reasons. High air permeance (low airtightness) has additional drawbacks: sound insulation degrades, drafts can occur, heat loss increases, and indoor surface temperatures might lower to a point where mold develops or surface condensation appears. Ground floors above crawlspaces must be airtight enough to prevent soil moisture, crawlspace odors, and radon from infiltrating into the conditioned space.

Acceptable envelope performance requires that the indoor surface temperature be high enough to prevent mold from occurring at the expected average vapor release indoors, the environmental conditions outdoors, the desired thermal comfort settings and the mean ventilation rate required for good IAQ and human health. Ventilation is also used to avoid acute surface condensation, which occurs each time the indoor dew-point temperature exceeds the envelope's indoor surface temperature somewhere (a common site is glazed surfaces). For a detailed analysis of mold and surface condensation, see Hens (1999), Sedlbauer (2001), Vereecken and Roels (2012), and Viitanen and Ojanen (2007).

With well-insulating, double- and triple-glazed, gas-filled, low-e windows in new construction and retrofits, water can also condense on the outdoor surface during cold, clear-sky nights, somewhat obscuring visibility.

Hot and Humid Climates

In hot and humid climates, to avoid mold growth and surface condensation, the indoor relative humidity should be kept below 60% through dehumidification. Brief periods of elevated relative humidity, however, do not necessarily result in mold germination. Keeping the building under positive air pressure is required to minimize interstitial condensation in wall cavities.

Dehumidification. Air-handling units that mix outdoor air with return air to provide constant airflows at variable supply temperatures do not provide continuous dehumidification. At higher supply air temperatures, the cooling coil does not remove moisture from the ventilation air, which can lead to elevated indoor relative humidity and a high potential for microbial growth. This becomes even more pronounced in energy-efficient buildings with reduced sensible cooling loads and long *off* times for the cooling coil, which significantly reduces the effectiveness of moisture removal (Rudd 2010; Rudd et al. 2005). For variable-supply-temperature systems, the ventilation air portion can be preconditioned using a dedicated outdoor air system (DOAS). These systems dehumidify only the ventilation air, and cooling loads are handled by a separate air-handling unit, so a DOAS is a good choice for providing continuously dehumidified ventilation air. If heat recovery is economically feasible without compromising pressurization, a DOAS with heat recovery is an energy-efficient alternative if the supply and return fans maintain correct pressurization, and the relative humidity of air passing through the supply filters remains low enough to avoid mold growth there. Because schools, office buildings, hospitals, and dwellings require continuous ventilation based on the number of occupants, demand-controlled DOAS-based outdoor ventilation air dehumidification can be achieved at a constant cooling-coil temperature. Reheat of the ventilation air may be required to avoid overcooling the supply air if ventilation demands are high. The resulting system provides more stable dehumidification and improved relative humidity control.

Alternatives for residential construction include local stand-alone dehumidifiers, with or without central system mixing; continuous exhaust/supply indoor air dehumidification using either a central HVAC system with subcooling followed by reheat, or ducted dehumidifiers; or ducted direct-expansion (DX) condenser-regenerated desiccant dehumidifiers (Harriman and Lstiburek 2009; Rudd 2013).

Pressurization. Dehumidification reduces the indoor vapor pressure below the outdoor vapor pressure level. Cooling does the same for temperature. As a result, the vapor pressure and temperature gradients cause moisture migration by diffusion toward the interior. If the envelope is not airtight, building depressurization and related infiltration increase this moisture flow through the exterior wall and connected partition wall cavities. This may raise the relative humidity at or near surfaces in these cavities to levels that allow mold, or even condensation. Pressurization reverses the airflow, allowing dehumidified indoor air to exfiltrate and neutralizing inward vapor diffusion. In any case, the envelope should be constructed as airtight as possible so that pressurization does not require unnecessarily high supply ventilation.

Cold Climates

In cold climates, the techniques for avoiding mold and surface condensation are the same as in temperate climates. During cold seasons, the indoor relative humidity can drop well below 30%. Maintaining healthy levels of relative humidity then requires humidification, which results in an increased indoor/outdoor vapor pressure difference for a temperature gradient pointing to the outdoors and vapor diffusion toward the exterior.

Humidification. At part load, on/off air-handling units that heat and humidify a mixture of outdoor and return air operate so intermittently that indoor relative humidity levels may drop substantially during off periods. Moisture buffering by the building fabric, furniture, and furnishings can reduce that variation in relative humidity (Simonson et al. 2004a, 2004b). A better choice in larger buildings is a DOAS that restricts humidification to the ventilation air, handling heating loads by a separate system. Because the ventilation required mainly depends on the number of occupants, the space can be humidified by using steam injection modulated according to demand, or by preheating the ventilation air followed by adiabatic humidification and reheat to the indoor temperature set point. The result is more stable humidification and better relative humidity control. Alternatives in homes are stand-alone humidifiers, continuous-supply air humidification at constant dew-point temperature by the central HVAC system, etc.

Pressurization/Depressurization. Pressurizing buildings in cold climates leads to air exfiltration, which provides an extra vehicle for vapor egress. Together with diffusion, this could lead to severe interstitial condensation in envelope assemblies, especially when the indoor vapor retarder is ineffective and the air barrier is not continuous. Depressurizing a building, which leads to infiltration, is as effective way to avoid interstitial condensation problems, as long as the envelope is sufficiently airtight that depressurization does not require ventilation rates beyond those needed by the occupant load. If the envelope is too air permeable, not only will large exhaust rates be required but all drawbacks mentioned in the section on Temperate and Mixed Climates will apply but be more severe.

9. MOISTURE MANAGEMENT IN OTHER HANDBOOK CHAPTERS

Other chapters and volumes of the *ASHRAE Handbook* also provide useful information on moisture and humidity.

In this volume,

Ch. 1 Perfect gas relations and thermodynamic properties to analyze conditions and processes involving moist air
4 Heat transfer processes that affect temperature and moisture transport in buildings

HVAC engineers and technicians require instruments for both laboratory work and fieldwork. Precision is more essential in the laboratory, where research and development are undertaken, than in the field, where acceptance and adjustment tests are conducted. This chapter describes the characteristics and uses of some of these instruments.

1. TERMINOLOGY

The following definitions are generally accepted.

Accuracy. Ability of an instrument to indicate the true value of measured quantity. This is often confused with inaccuracy, which is the departure from the true value to which all causes of error (e.g., hysteresis, nonlinearity, drift, temperature effect) contribute.

Amplitude. Magnitude of variation from its equilibrium or average value in an alternating quantity.

Average. Sum of a number of values divided by the number of values.

Bandwidth. Range of frequencies over which a given device is designed to operate within specified limits.

Bias. Tendency of an estimate to deviate in one direction from a true value (a systematic error).

Calibration. (1) Process of comparing a set of discrete magnitudes or the characteristic curve of a continuously varying magnitude with another set or curve previously established as a standard. Deviation between indicated values and their corresponding standard values constitutes the correction (or calibration curve) for inferring true magnitude from indicated magnitude thereafter; (2) process of adjusting an instrument to fix, reduce, or eliminate the deviation defined in (1). Calibration reduces bias (systematic) errors.

Calibration curve. (1) Path or locus of a point that moves so that its graphed coordinates correspond to values of input signals and output deflections; (2) plot of error versus input (or output).

Confidence. Degree to which a statement (measurement) is believed to be true.

Dead band. Range of values of the measured variable to which an instrument will not effectively respond. The effect of dead band is similar to hysteresis, as shown in Figure 1.

Deviate. Any item of a statistical distribution that differs from the selected measure of control tendency (average, median, mode).

Deviation. Difference between a single measured value and the mean (average) value of a population or sample.

Diameter, equivalent. The diameter of a circle having the same area as the rectangular flow channel cross section.

Deviation, standard. Square root of the average of the squares of the deviations from the mean (root mean square deviation). A measure of dispersion of a population.

Distortion. Unwanted change in wave form. Principal forms of distortion are inherent nonlinearity of the device, nonuniform response at different frequencies, and lack of constant proportionality between phase-shift and frequency. (A wanted or intentional change might be identical, but it is called **modulation**.)

Drift. Gradual, undesired change in output over a period of time that is unrelated to input, environment, or load. Drift is gradual; if variation is rapid and recurrent, with elements of both increasing and decreasing output, the fluctuation is referred to as **cycling**.

Dynamic error band. Spread or band of output-amplitude deviation incurred by a constant-amplitude sine wave as its frequency is varied over a specified portion of the frequency spectrum (see *Static error band*).

Emissivity. Ratio of the amount of radiation emitted by a real surface to that of an ideal (blackbody) emitter at the same temperature.

Error. Difference between the true or actual value to be measured (input signal) and the indicated value (output) from the measuring system. Errors can be systematic or random.

Error, accuracy. See *Error, systematic*.

Error, fixed. See *Error, systematic*.

Error, instrument. Error of an instrument's measured value that includes random or systematic errors.

Error, precision. See *Error, random*.

Error, probable. Error with a 50% or higher chance of occurrence. A statement of probable error is of little value.

Error, random. Statistical error caused by chance and not recurring. This term is a general category for errors that can take values on either side of an average value. To describe a random error, its distribution must be known.

Error, root mean square (RMS). Accuracy statement of a system comprising several items. For example, a laboratory potentiometer, volt box, null detector, and reference voltage source have individual accuracy statements assigned to them. These errors are generally independent of one another, so a system of these units displays an accuracy given by the square root of the sum of the squares of the individual limits of error. For example, four individual errors of 0.1% could yield a calibrated error of 0.4% but an RMS error of only 0.2%.

Error, systematic. Persistent error not caused by chance; systematic errors are causal. It is likely to have the same magnitude and sign for every instrument constructed with the same components and

The preparation of this chapter is assigned to TC 1.2, Instruments and Measurements.

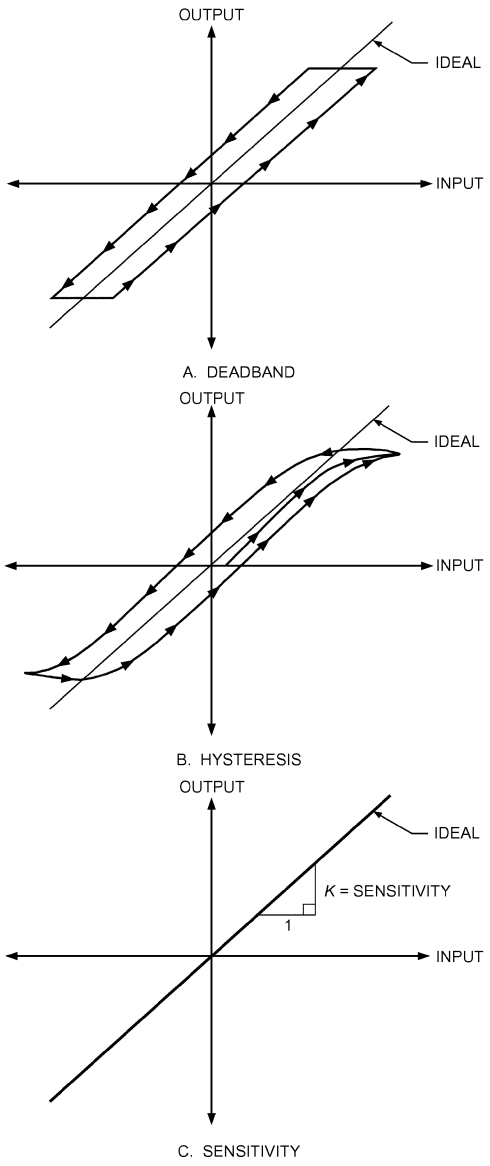

Fig. 1 Measurement and Instrument Terminology

procedures. Errors in calibrating equipment cause systematic errors because all instruments calibrated are biased in the direction of the calibrating equipment error. Voltage and resistance drifts over time are generally in one direction and are classed as systematic errors.

Frequency response (flat). Portion of the frequency spectrum over which the measuring system has a constant value of amplitude response and a constant value of time lag. Input signals that have frequency components within this range are indicated by the measuring system (without distortion).

Hydraulic diameter D_h. Defined as $4A_c/P_{wet}$, where A_c is flow cross-sectional area and P_{wet} is the wetted perimeter (perimeter in contact with the flowing fluid). For a rectangular duct with dimensions $W \times H$, the hydraulic diameter is $D_h = 2HW/(H + W)$. The related quantity *effective* or *equivalent diameter* is defined as the diameter of a circular tube having the same cross-sectional area as the actual flow channel. For a rectangular flow channel, the effective diameter is $D_{eff} = \sqrt{4HW/\pi}$.

Hysteresis. Summation of all effects, under constant environmental conditions, that cause an instrument's output to assume different values at a given stimulus point when that point is approached with increasing or decreasing stimulus. Hysteresis includes backlash. It is usually measured as a percent of full scale when input varies over the full increasing and decreasing range. In instrumentation, hysteresis and dead band exhibit similar output error behavior in relation to input, as shown in Figure 1.

Linearity. The degree of straightness of the transfer curve between an input and an output (e.g., the ideal line in Figure 1); that condition prevailing when output is directly proportional to input (see *Nonlinearity*). Note that the generic term *linearity* does not consider any parallel offset of the straight-line calibration curve.

Loading error. Loss of output signal from a device caused by a current drawn from its output. It increases the voltage drop across the internal impedance, where no voltage drop is desired.

Mean. See *Average*.

Median. Middle value in a distribution, above and below which lie an equal number of values.

Mode. Value in a distribution that occurs most frequently.

Noise. Any unwanted disturbance or spurious signal that modifies the transmission, measurement, or recording of desired data.

Nonlinearity. Prevailing condition (and the extent of its measurement) under which the input/output relationship (known as the input/output curve, transfer characteristic, calibration curve, or response curve) fails to be a straight line. Nonlinearity is measured and reported in several ways, and the way, along with the magnitude, must be stated in any specification.

Minimum-deviation-based nonlinearity: maximum departure between the calibration curve and a straight line drawn to give the greatest accuracy; expressed as a percent of full-scale deflection.

Slope-based nonlinearity: ratio of maximum slope error anywhere on the calibration curve to the slope of the nominal sensitivity line; usually expressed as a percent of nominal slope.

Most other variations result from the many ways in which the straight line can be arbitrarily drawn. All are valid as long as construction of the straight line is explicit.

Population. Group of individual persons, objects, or items from which samples may be taken for statistical measurement.

Precision. Repeatability of measurements of the same quantity under the same conditions; not a measure of absolute accuracy. It describes the relative tightness of the distribution of measurements of a quantity about their mean value. Therefore, precision of a measurement is associated more with its repeatability than its accuracy. It combines uncertainty caused by random differences in a number of identical measurements and the smallest readable increment of the scale or chart. Precision is given in terms of deviation from a mean value.

Primary calibration. Calibration procedure in which the instrument output is observed and recorded while the input stimulus is applied under precise conditions, usually from a primary external standard traceable directly to the National Institute of Standards and Technology (NIST) or to an equivalent international standards organization.

Range. Statement of upper and lower limits between which an instrument's input can be received and for which the instrument is calibrated.

Reliability. Probability that an instrument's precision and accuracy will continue to fall within specified limits.

Repeatability. See *Precision*.

Reproducibility. In instrumentation, the closeness of agreement among repeated measurements of the output for the same value of input made under the same operating conditions over a period of time, approaching from both directions; it is usually measured as a nonreproducibility and expressed as reproducibility in percent of span for a specified time period. Normally, this implies a long period of time, but under certain conditions, the period may be a short time so that drift is not included. Reproducibility includes

Licensed for single user. © 2021 ASHRAE, Inc.

hysteresis, dead band, drift, and repeatability. Between repeated measurements, the input may vary over the range, and operating conditions may vary within normal limits.

Resolution. Smallest change in input that produces a detectable change in instrument output. Resolution, unlike precision, is a psychophysical term referring to the smallest increment of humanly perceptible output (rated in terms of the corresponding increment of input). The precision, resolution, or both may be better than the accuracy. An ordinary six-digit instrument has a resolution of one part per million (ppm) of full scale; however, it is possible that the accuracy is no better than 25 ppm (0.0025%). Note that the practical resolution of an instrument cannot be any better than the resolution of the indicator or detector, whether internal or external.

Sensitivity. Slope of a calibration curve relating input signal to output, as shown in Figure 1. For linear instruments, sensitivity represents the change in output for a unit change in the input.

Sensitivity error. Maximum error in sensitivity displayed as a result of the changes in the calibration curve resulting from accumulated effects of systematic and random errors.

Stability. (1) Independence or freedom from changes in one quantity as the result of a change in another; (2) absence of drift.

Static error band. (1) Spread of error present if the indicator (pen, needle) stopped at some value (e.g., at one-half of full scale), normally reported as a percent of full scale; (2) specification or rating of maximum departure from the point where the indicator must be when an on-scale signal is stopped and held at a given signal level. This definition stipulates that the stopped position can be approached from either direction in following any random waveform. Therefore, it is a quantity that includes hysteresis and nonlinearity but excludes items such as chart paper accuracy or electrical drift (see *Dynamic error band*).

Step-function response. Characteristic curve or output plotted against time resulting from the input application of a step function (a function that is zero for all values of time before a certain instant, and a constant for all values of time thereafter).

Threshold. Smallest stimulus or signal that results in a detectable output. *Resolution* and threshold are sometimes used interchangeably.

Time constant. Time required for an exponential quantity to change by an amount equal to 0.632 times the total change required to reach steady state for first-order systems.

Transducer. Device for translating the changing magnitude of one kind of quantity into corresponding changes of another kind of quantity. The second quantity often has dimensions different from the first and serves as the source of a useful signal. The first quantity may be considered an input and the second an output. Significant energy may or may not transfer from the transducer's input to output.

Uncertainty. An estimated value for the bound on the error (i.e., what an error might be if it were measured by calibration). Although uncertainty may be the result of both systematic and precision errors, only precision error can be treated by statistical methods. Uncertainty may be either **absolute** (expressed in the units of the measured variable) or **relative** (absolute uncertainty divided by the measured value; commonly expressed in percent).

Zero shift. Drift in the zero indication of an instrument without any static change in the measured variable.

2. UNCERTAINTY ANALYSIS

Uncertainty Sources

Measurement generally consists of a sequence of operations or steps. Virtually every step introduces a conceivable source of uncertainty, the effect of which must be assessed. The following list is representative of the most common, but not all, sources of uncertainty.

- Inaccuracy in the mathematical model that describes the physical quantity
- Inherent stochastic variability of the measurement process
- Uncertainties in measurement standards and calibrated instrumentation
- Time-dependent instabilities caused by gradual changes in standards and instrumentation
- Effects of environmental factors such as temperature, humidity, and pressure
- Values of constants and other parameters obtained from outside sources
- Uncertainties arising from interferences, impurities, inhomogeneity, inadequate resolution, and incomplete discrimination
- Computational uncertainties and data analysis
- Incorrect specifications and procedural errors
- Laboratory practice, including handling techniques, cleanliness, and operator techniques, etc.
- Uncertainty in corrections made for known effects, such as installation effect corrections

Uncertainty of a Measured Variable

For a measured variable X, the total error is caused by both **precision (random)** and **systematic (bias) errors**. This relationship is shown in Figure 2. The possible measurement values of the variable are scattered in a distribution around the parent population mean μ (Figure 2A). The curve (**normal** or **Gaussian distribution**) is the theoretical distribution function for the infinite population of measurements that generated X. The parent population mean differs from $(X)_{true}$ by an amount called the systematic (or bias) error β (Figure 2B). The quantity β is the total fixed error that remains after all calibration corrections have been made. In general, there are several sources of bias error, such as errors in calibration standard, data acquisition, data reduction, and test technique. There is usually no direct way to measure these errors. These errors are unknown and are assumed to be zero; otherwise, an additional correction would

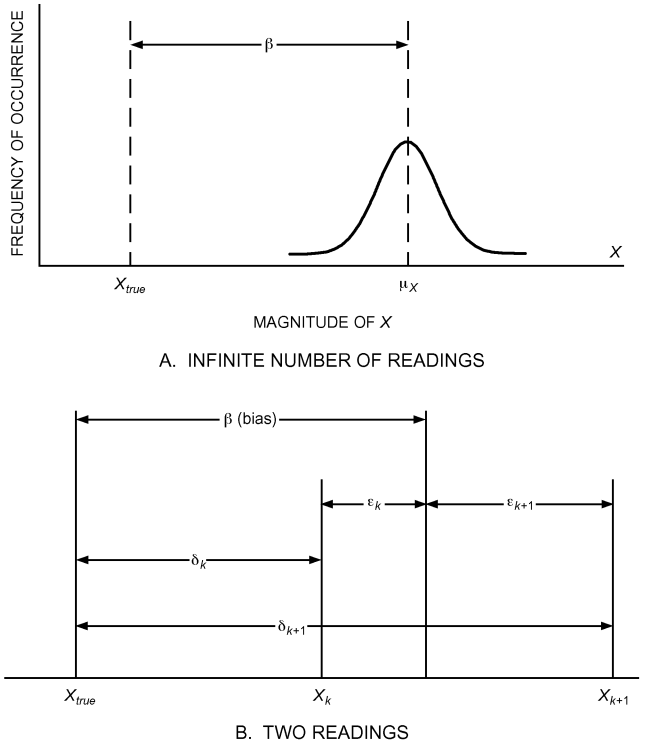

Fig. 2 Errors in Measurement of Variable X

Licensed for single user. © 2021 ASHRAE, Inc.

be applied to reduce them to as close to zero as possible. Figure 2B shows how the resulting deviation δ can be different for different random errors ε.

The **precision uncertainty** for a variable, which is an estimate of the possible error associated with the repeatability of a particular measurement, is determined from the sample standard deviation, or the estimate of the error associated with the repeatability of a particular measurement. Unlike systematic error, precision error varies from reading to reading. As the number of readings of a particular variable tends to infinity, the distribution of these possible errors becomes Gaussian.

For each bias error source, the experimenter must estimate a **systematic uncertainty**. Systematic uncertainties are usually estimated from previous experience, calibration data, analytical models, and engineering judgment. The resultant uncertainty is the square root of the sum of the squares of the bias and precision uncertainties; see Coleman and Steele (2009).

For further information on measurement uncertainty, see Abernethy et al. (1985), ASME *Standards* MFC-2M and PTC 19.1, Brown et al. (1998), and Coleman and Steele (1995).

3. TEMPERATURE MEASUREMENT

Instruments for measuring temperature are listed in Table 1. Temperature sensor output must be related to an accepted temperature scale by manufacturing the instrument according to certain specifications or by calibrating it against a temperature standard. To help users conform to standard temperatures and temperature measurements, the International Committee of Weights and Measures (CIPM) adopted the International Temperature Scale of 1990 (ITS-90).

The unit of temperature of the ITS-90 is the kelvin (K) and has a size equal to the fraction 1/273.16 of the thermodynamic temperature of the triple point of water.

In the United States, ITS-90 is maintained by the National Institute of Standards and Technology (NIST), which provides calibrations based on this scale for laboratories.

Benedict (1984), Considine (1985), DeWitt and Nutter (1988), Holman (2001), Quinn (1990), and Schooley (1986, 1992) cover temperature measurement in more detail.

Sampling and Averaging

Although temperature is usually measured within, and is associated with, a relatively small volume (depending on the size of the thermometer), it can also be associated with an area (e.g., on a surface or in a flowing stream). To determine average stream temperature, the cross section must be divided into smaller areas and the temperature of each area measured. The temperatures measured are then combined into a weighted mass flow average by using either (1) equal areas and multiplying each temperature by

Table 1 Common Temperature Measurement Techniques

Measurement Means	Application	Approximate Range, °C	Uncertainty, K	Limitations
Liquid-in-glass thermometers				
Mercury-in-glass	Temperature of gases and liquids by contact	–38/550	0.03 to 2	In gases, accuracy affected by radiation (unless adequately shielded)
Organic fluid	Temperature of gases and liquids by contact	–200/200	0.03 to 2	In gases, accuracy affected by radiation
Resistance thermometers				
Platinum	Precision; remote readings; temperature of fluids or solids by contact	–259/1000	Less than 0.0001 to 0.1	High cost; accuracy affected by radiation in gases
Rhodium/iron	Transfer standard for cryogenic applications	–273/–243	0.0001 to 0.1	High cost
Nickel	Remote readings; temperature by contact	–250/200	0.01 to 1	Accuracy affected by radiation in gases
Germanium	Remote readings; temperature by contact	–273/–243	0.0001 to 0.1	
Thermistors	Remote readings; temperature by contact	–90/200	0.0001 to 0.1	
Thermocouples				
Pt-Rh/Pt (type S)	Standard for thermocouples on IPTS-68, not on ITS-90	0/1450	0.1 to 3	High cost
Au/Pt	Highly accurate reference thermometer for laboratory applications	–50/1000	0.05 to 1	High cost
Types K and N	General testing of high temperature; remote rapid readings by direct contact	–200/1250	0.1 to 10	Less accurate than Pt-Rh/Pt or Au/Pt thermocouples
Iron/Constantan (type J)	Same as above	0 to 760	0.1 to 6	Subject to oxidation
Copper/Constantan (type T)	Same as above; especially suited for low temperature	–200/370	0.1 to 3	
Ni-Cr/Constantan (type E)	Same as above; especially suited for low temperature	–200/900	0.1 to 7	
Bimetallic thermometers	For approximate temperature	–20/660	1, usually much more	Time lag; unsuitable for remote use
Pressure-bulb thermometers				
Gas-filled bulb	Remote reading	–75/660	2	Use caution to ensure installation is correct
Vapor-filled bulb	Remote testing	–5/250	2	Use caution to ensure installation is correct
Liquid-filled bulb	Remote testing	–50/1150	2	Use caution to ensure installation is correct
Optical pyrometers	For intensity of narrow spectral band of high-temperature radiation (remote)	800 and up	15	Generally requires knowledge of surface emissivity
Infrared (IR) radiometers	For intensity of total high-temperature radiation (remote)	Any range		
IR thermography	Infrared imaging	Any range		Generally requires knowledge of surface emissivity
Seger cones (fusion pyrometers)	Approximate temperature (within temperature source)	660/2000	50	

Licensed for single user. © 2021 ASHRAE, Inc.

the fraction of total mass flow in its area or (2) areas of size inversely proportional to mass flow and taking a simple arithmetic average of the temperatures in each. Mixing or selective sampling may be preferable to these cumbersome procedures. Although mixing can occur from turbulence alone, **transposition** is much more effective. In transposition, the stream is divided into parts determined by the type of stratification, and alternate parts pass through one another.

Static Temperature Versus Total Temperature

When a fluid stream impinges on a temperature-sensing element such as a thermometer or thermocouple, the element is at a temperature greater than the true stream temperature. The difference is a fraction of the temperature equivalent of the stream velocity t_e.

$$t_e = \frac{V^2}{2Jc_p} \tag{1}$$

where

t_e = temperature equivalent of stream velocity, °C
V = stream velocity, m/s
J = mechanical equivalent of heat = 1000 (N·m)/kJ
c_p = specific heat of stream at constant pressure, kJ/(kg·K)

This fraction of the temperature equivalent of the velocity is the **recovery factor**, which varies from 0.3 to 0.4 K for bare thermometers to 0.5 K for aerodynamically shielded thermocouples. For precise temperature measurement, each temperature sensor must be calibrated to determine its recovery factor. However, for most applications with air velocities below 10 m/s (or Mach number M below approximately 0.1), the recovery factor can be omitted.

Various sensors are available for temperature measurement in fluid streams. The principal ones are the **static temperature thermometer**, which indicates true stream temperature but is cumbersome, and the **thermistor**, used for accurate temperature measurement within a limited range.

3.1 LIQUID-IN-GLASS THERMOMETERS

Any device that changes monotonically with temperature is a thermometer; however, the term usually signifies an ordinary liquid-in-glass temperature-indicating device. Mercury-filled thermometers have a useful range from –38.8°C, the freezing point of mercury, to about 550°C, near which the glass usually softens. Lower temperatures can be measured with organic-liquid-filled thermometers (e.g., alcohol-filled), with ranges of –200 to 200°C. During manufacture, thermometers are roughly calibrated for at least two temperatures, often the freezing and boiling points of water; space between the calibration points is divided into desired scale divisions. Thermometers that are intended for precise measurement applications have scales etched into the glass that forms their stems. The probable error for as-manufactured, etched-stem thermometers is ±1 scale division. The highest-quality mercury thermometers may have uncertainties of ±0.03 to 2 K if they have been calibrated by comparison against primary reference standards.

Liquid-in-glass thermometers are used for many HVAC applications, including local temperature indication of process fluids (e.g., cooling and heating fluids and air).

Mercury-in-glass thermometers are fairly common as temperature measurement standards because of their relatively high accuracy and low cost. If used as references, they must be calibrated on the ITS-90 by comparison in a uniform bath with a standard platinum resistance thermometer that has been calibrated either by the appropriate standards agency or by a laboratory that has direct traceability to the standards agency and the ITS-90. This calibration is necessary to determine the proper corrections to be applied to the scale readings. For application and calibration of liquid-in-glass thermometers, refer to NIST (1976, 1986).

Liquid-in-glass thermometers are calibrated by the manufacturer for total or partial stem immersion. If a thermometer calibrated for total immersion is used at partial immersion (i.e., with part of the liquid column at a temperature different from that of the bath), an emergent stem correction must be made, as follows:

$$\text{Stem correction} = Kn(t_b - t_s) \tag{2}$$

where

K = differential expansion coefficient of mercury or other liquid in glass. K is 0.00016 for Celsius mercury thermometers. For K values for other liquids and specific glasses, refer to Schooley (1992).
n = number of degrees that liquid column emerges from bath
t_b = temperature of bath, °C
t_s = average temperature of emergent liquid column of n degrees, °C

Because the true temperature of the bath is not known, this stem correction is only approximate.

Sources of Thermometer Errors

A thermometer measuring gas temperatures can be affected by radiation from surrounding surfaces. If the gas temperature is approximately the same as that of the surrounding surfaces, radiation effects can be ignored. If the temperature differs considerably from that of the surroundings, radiation effects should be minimized by shielding or aspiration (ASME *Standard* PTC 19.3). **Shielding** may be provided by highly reflective surfaces placed between the thermometer bulb and the surrounding surfaces such that air movement around the bulb is not appreciably restricted (Parmelee and Huebscher 1946). Improper shielding can increase errors. **Aspiration** involves passing a high-velocity stream of air or gas over the thermometer bulb.

When a **thermometer well** within a container or pipe under pressure is required, the thermometer should fit snugly and be surrounded with a high-thermal-conductivity material (oil, water, or mercury, if suitable). Liquid in a long, thin-walled well is advantageous for rapid response to temperature changes. The surface of the pipe or container around the well should be insulated to eliminate heat transfer to or from the well.

Industrial thermometers are available for permanent installation in pipes or ducts. These instruments are fitted with metal guards to prevent breakage. However, the considerable heat capacity and conductance of the guards or shields can cause errors.

Allowing ample time for the thermometer to attain temperature equilibrium with the surrounding fluid prevents excessive errors in temperature measurements. When reading a liquid-in-glass thermometer, keep the eye at the same level as the top of the liquid column to avoid parallax.

3.2 RESISTANCE THERMOMETERS

Resistance thermometers depend on a change of the electrical resistance of a sensing element (usually metal) with a change in temperature; resistance increases with increasing temperature. Use of resistance thermometers largely parallels that of thermocouples, although readings are usually unstable above about 550°C. Two-lead temperature elements are not recommended because they do not allow correction for lead resistance. Three leads to each resistor are necessary for consistent readings, and four leads are preferred. Wheatstone bridge circuits or 6-1/2-digit multimeters can be used for measurements.

A typical circuit used by several manufacturers is shown in Figure 3. This design uses a differential galvanometer in which coils L and H exert opposing forces on the indicating needle. Coil L is in

Licensed for single user. © 2021 ASHRAE, Inc.

series with the thermometer resistance AB, and coil H is in series with the constant resistance R. As the temperature falls, the resistance of AB decreases, allowing more current to flow through coil L than through coil H. This increases the force exerted by coil L, pulling the needle down to a lower reading. Likewise, as the temperature rises, the resistance of AB increases, causing less current to flow through coil L than through coil H and forcing the indicating needle to a higher reading. Rheostat S must be adjusted occasionally to maintain constant current.

The resistance thermometer is more costly to make and likely to have considerably longer response times than thermocouples. It gives best results when used to measure steady or slowly changing temperature.

Resistance Temperature Devices

Resistance temperature devices (RTDs) are typically constructed from platinum, rhodium/iron, nickel, nickel/iron, tungsten, or copper. These devices are further characterized by their simple circuit designs, high degree of linearity, good sensitivity, and excellent stability. The choice of materials for an RTD usually depends on the intended application; selection criteria include temperature range, corrosion protection, mechanical stability, and cost.

Presently, for HVAC applications, RTDs constructed of platinum are the most widely used. Platinum is extremely stable and resistant to corrosion. Platinum RTDs are highly malleable and can thus be drawn into fine wires; they can also be manufactured inexpensively as thin films. They have a high melting point and can be refined to high purity, thus attaining highly reproducible results. Because of these properties, platinum RTDs are used to define the ITS-90 for the range of 13.8033 K (triple point of equilibrium hydrogen) to 1234.93 K (freezing point of silver).

Platinum resistance temperature devices can measure the widest range of temperatures and are the most accurate and stable temperature sensors. Their resistance/temperature relationship is one of the most linear. The higher the purity of the platinum, the more stable and accurate the sensor. With high-purity platinum, primary-grade platinum RTDs can achieve reproducibility of ±0.00001 K, whereas the minimum uncertainty of a recently calibrated thermocouple is ±0.2 K.

The most widely used RTD is designed with a resistance of 100 Ω at 0°C (R_0 = 100 Ω). Other RTDs are available that use lower resistances at temperatures above 600°C. The lower the resistance value, the faster the response time for sensors of the same size.

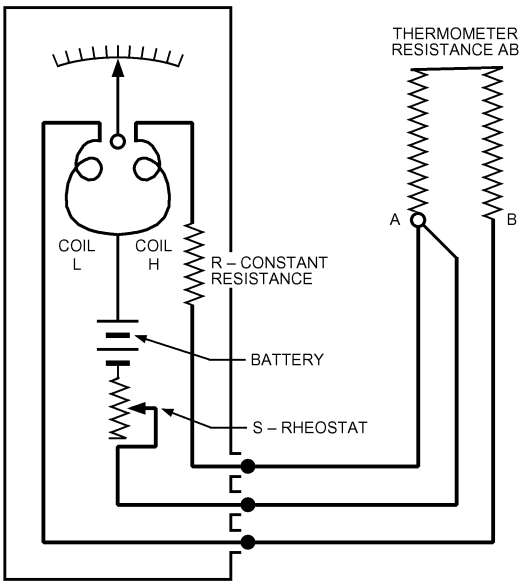

Fig. 3 Typical Resistance Thermometer Circuit

Thin-Film RTDs. Thin-film 1000 Ω platinum RTDs are readily available. They have the excellent linear properties of lower-resistance platinum RTDs and are more cost-effective because they are mass produced and have lower platinum purity. However, many platinum RTDs with R_0 values of greater than 100 Ω are difficult to provide with transmitters or electronic interface boards from sources other than the RTD manufacturer. In addition to a nonstandard interface, higher-R_0-value platinum RTDs may have higher self-heating losses if the excitation current is not controlled properly.

Thin-film RTDs have the advantages of lower cost and smaller sensor size. They are specifically adapted to surface mounting. Thin-film sensors tend to have an accuracy limitation of ±0.1% or ±0.1 K. This may be adequate for most HVAC applications; only in tightly controlled facilities may users wish to install the standard wire-wound platinum RTDs with accuracies of 0.01% or ±0.01 K (available on special request for certain temperature ranges).

Assembly and Construction. Regardless of the R_0 value, RTD assembly and construction are relatively simple. Electrical connections come in three basic types, depending on the number of wires to be connected to the resistance measurement circuitry. Two, three, or four wires are used for electrical connection using a Wheatstone bridge or a variation (Figure 4).

In the basic two-wire configuration, the RTD's resistance is measured through the two connecting wires. Because the connecting wires extend from the site of the temperature measurement, any additional changes in resistivity caused by a change in temperature may affect the measured resistance. Three- and four-wire assemblies are built to compensate for the connecting lead resistance values. The original three-wire circuit improved resistance measurement by adding a compensating wire to the voltage side of the circuit. This helps reduce part of the connecting wire resistance. When more accurate measurements (better than ±0.1 K) are required, the four-wire bridge, which eliminates all connecting wire resistance errors, is recommended.

All bridges discussed here are direct current (DC) circuits and were used extensively until the advent of precision alternating current (AC) circuits using microprocessor-controlled ratio transformers, dedicated analog-to-digital converters, and other solid-state devices that measure resistance with uncertainties of less than 1 ppm. Resistance measurement technology now allows more portable thermometers, lower cost, ease of use, and high-precision temperature measurement in industrial uses.

Thermistors

Some semiconductor compounds (usually sintered metallic oxides) exhibit large changes in resistance with temperature, usually decreasing as the temperature increases. For use, the thermistor element may be connected by lead wires into a galvanometer bridge circuit and calibrated. Alternatively, a 6-1/2-digit multimeter and a constant-current source with a means for reversing the current to eliminate thermal electromotive force (emf) effects may also be used. This method is easier and faster, and may be more precise and accurate. Thermistors are usually applied to electronic temperature compensation circuits, such as thermocouple reference junction compensation, or to other applications requiring high resolution and having limited operating-temperature ranges. Figure 5 shows a typical thermistor circuit.

Semiconductor Devices

In addition to positive-resistance-coefficient RTDs and negative-resistance-coefficient thermistors, there are two other types of devices that vary resistance or impedance with temperature. Although the principle of their operation has long been known, their reliability was questioned because of imprecise manufacturing techniques.

Licensed for single user. © 2021 ASHRAE, Inc.

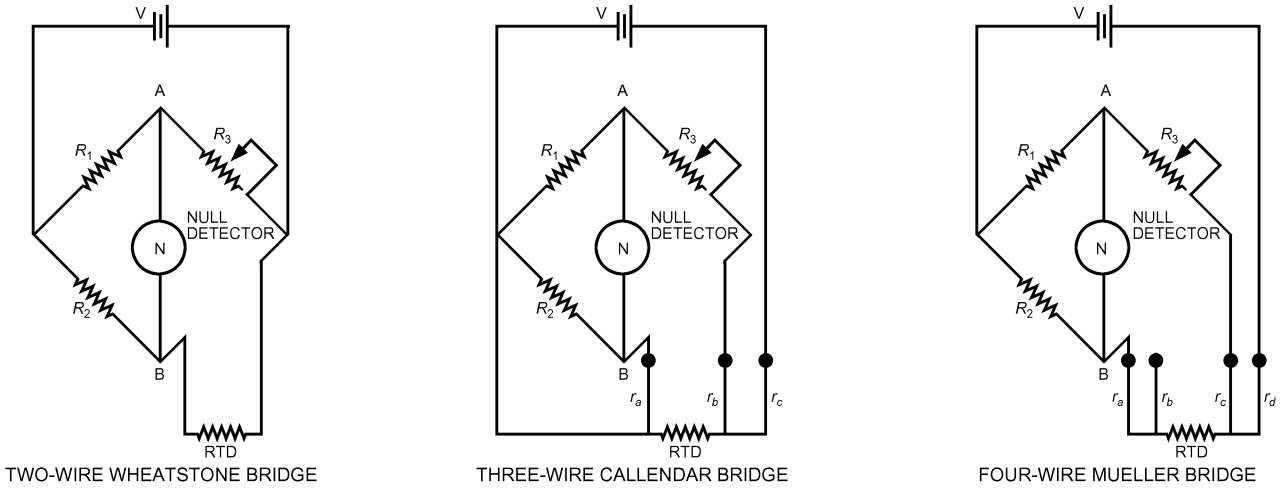

Fig. 4 Typical Resistance Temperature Device (RTD) Bridge Circuits

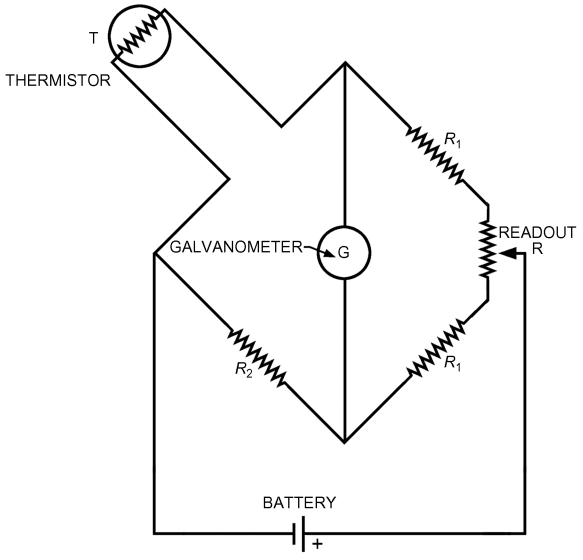

Fig. 5 Basic Thermistor Circuit

Improved silicon microelectronics manufacturing techniques have brought semiconductors to the point where low-cost, precise temperature sensors are commercially available.

Elemental Semiconductors. Because of controlled doping of impurities into elemental germanium, a germanium semiconductor is a reliable temperature sensor for cryogenic temperature measurement in the range of 1 to 84 K.

Junction Semiconductors. The first simple junction semiconductor device consisted of a single diode or transistor, in which the forward-connected base emitter voltage was very sensitive to temperature. Today, the more common form is a pair of diode-connected transistors, which make the device suitable for ambient temperature measurement. Applications include thermocouple reference junction compensation.

The primary advantages of silicon transistor temperature sensors are their extreme linearity and exact R_0 value, as well as the incorporation of signal conditioning circuitry into the same device as the sensor element. As with thermocouples, these semiconductors require highly precise manufacturing techniques, extremely precise voltage measurements, multiple-point calibration, and temperature compensation to achieve an accuracy as high as ±0.01 K, but with a much higher cost. Lower-cost devices achieve accuracies of ±0.1 K using mass-manufacturing techniques and single-point calibration. A mass-produced silicon temperature sensor can be interchanged easily. If one device fails, only the sensor element need be changed. Electronic circuitry can be used to recalibrate the new device.

Winding Temperature. The winding temperature of electrical operating equipment is usually determined from the resistance change of these windings in operation. The relationship between the winding resistance R_1 at a known temperature t_1 and the winding resistance at any other temperature t_2 is given by Equation (3) (IEEE *Standard* 112-2004).

$$\frac{R_2}{R_1} = \frac{\left[\frac{1}{\alpha} - t_0\right] + t_2}{\left[\frac{1}{\alpha} - t_0\right] + t_1} = \frac{k + t_2}{k + t_1} \tag{3}$$

where

R_1 = winding resistance at temperature t_1, Ω
R_2 = winding resistance at temperature t_2, Ω
t_1, t_2 = winding temperatures, °C
α = wire resistivity coefficient, °C^{-1}
t_0 = reference temperature for resistivity, 25°C
k = $1/\alpha - t_0$ = winding material constant, 390.1°C for 100% IACS conductivity copper

The classical method of determining winding temperature is to measure the equipment when it is inoperative and temperature-stabilized at room temperature. After the equipment has operated sufficiently to stabilize temperature under load conditions, the winding resistance should be measured again by taking resistance measurements at known, short time intervals after shutdown. These values may be extrapolated to zero time to indicate the winding resistance at the time of shutdown. The obvious disadvantage of this method is that the device must be shut down to determine winding temperature. A circuit described by Seely (1955), however, makes it possible to measure resistances while the device is operating.

3.3 THERMOCOUPLES

When two wires of dissimilar metals are joined by soldering, welding, or twisting, they form a thermocouple junction or **thermojunction**. An emf that depends on the wire materials and the junction temperature exists between the wires. This is known as the **Seebeck voltage**.

Table 2 Thermocouple Tolerances on Initial Values of Electromotive Force Versus Temperature

Thermocouple Type	Material Identification	Temperature Range, °C	Reference Junction Tolerance at 0°C[a]	
			Standard Tolerance (Whichever Is Greater)	Special Tolerance (Whichever Is Greater)
T	Copper versus constantan	0 to 350	±1 K or ±0.75%	±0.5 K or ±0.4%
J	Iron versus constantan	0 to 750	±2.2 K or ±0.75%	±1.1 K or ±0.4%
E	Nickel/10% chromium versus constantan	0 to 900	±1.7 K or ±0.5%	±1 K or ±0.4%
K	Nickel/10% chromium versus 5% aluminum, silicon	0 to 1250	±2.2 K or ±0.75%	±1.1 K or ±0.4%
N	Nickel/14% chromium, 1.5% silicon versus nickel/4.5% silicon, 0.1% magnesium	0 to 1250	±2.2 K or ±0.75%	±1.1 K or ±0.4%
R	Platinum/13% rhodium versus platinum	0 to 1450	±1.5 K or ±0.25%	±0.6 K or ±0.1%
S	Platinum/10% rhodium versus platinum	0 to 1450	±1.5 K or ±0.25%	±0.6 K or ±0.1%
B	Platinum/30% rhodium versus platinum/6% rhodium	870 to 1700	±0.5%	±0.25%
T[b]	Copper versus constantan	–200 to 0	±1 K or ±1.5%	c
E[b]	Nickel/10% chromium versus constantan	–200 to 0	±1.7 K or ±1%	c
K[b]	Nickel/10% chromium versus 5% aluminum, silicon	–200 to 0	±2.2 K or ±2%	c c

Source: ASTM *Standard* E230.

[a]Tolerances in this table apply to new thermocouple wire, normally in the size range of 0.25 to 3 mm diameter and used at temperatures not exceeding recommended limits. Thermocouple wire is available in two grades: standard and special.

[b]Thermocouples and thermocouple materials are normally supplied to meet the tolerance specified in the table for temperatures above 0°C. The same materials, however, may not fall within the tolerances given in the second section of the table when operated below freezing (0°C). If materials are required to meet tolerances at subfreezing temperatures, the purchase order must state so.

[c]Little information is available to justify establishing special tolerances for below-freezing temperatures. Limited experience suggests the following special tolerances for types E and T thermocouples:

Type E –200 to 0°C; ±1 K or ±0.5% (whichever is greater)

Type T –200 to 0°C; ±0.5 K or ±0.8% (whichever is greater)

These tolerances are given only as a guide for discussion between purchaser and supplier.

Licensed for single user. © 2021 ASHRAE, Inc.

Thermocouples for temperature measurement yield less precise results than platinum resistance thermometers, but, except for glass thermometers, thermocouples are the most common instruments of temperature measurement for the range of 0 to 1000°C. Because of their low cost, moderate reliability, and ease of use, thermocouples are widely accepted.

The most commonly used thermocouples in industrial applications are assigned letter designations. Tolerances of such commercially available thermocouples are given in Table 2.

Because the measured emf is a function of the difference in temperature and the type of dissimilar metals used, a known temperature at one junction is required; the remaining junction temperature may be calculated. It is common to call the one with known temperature the (cold) **reference** junction and the one with unknown temperature the (hot) **measured** junction. The reference junction is typically kept at a reproducible temperature, such as the ice point of water.

Various systems are used to maintain the reference junction temperature (e.g., mixed ice and water in an insulated flask, commercially available thermoelectric coolers to maintain the ice-point temperature automatically in a reference chamber). When these systems cannot be used in an application, measuring instruments with automatic reference junction temperature compensation may be used. These types of instruments typically use a thermistor or RTD to measure the reference junction temperature to provide reference junction temperature compensation.

As previously described, the principle for measuring temperature with a thermocouple is based on accurate measurement of the Seebeck voltage. Acceptable DC voltage measurement methods are (1) millivoltmeter, (2) millivolt potentiometer, and (3) high-input impedance digital voltmeter. Many digital voltmeters include built-in software routines for direct calculation and display of temperature. Regardless of the method selected, there are many ways to simplify measurement.

Solid-state digital readout devices in combination with a milli- or microvoltmeter, as well as packaged thermocouple readouts with built-in cold junction and linearization circuits, are available. The latter requires a proper thermocouple to provide direct meter reading of temperature. Accuracy approaching or surpassing that of potentiometers can be attained, depending on the instrument quality. This method is popular because it eliminates the null balancing requirement and reads temperature directly in a digital readout.

Wire Diameter and Composition

Thermocouple wire is selected by considering the temperature to be measured, the corrosion protection afforded to the thermocouple, and the precision and service life required. Type T thermocouples are suitable for temperatures up to 350°C; type J, up to 750°C; and types K and N, up to 1250°C. Higher temperatures require noble metal thermocouples (type S, R, or B), which have a higher initial cost and do not develop as high an emf as the base metal thermocouples. Thermocouple wires of the same type have small compositional variation from lot to lot from the same manufacturer, and especially among different manufacturers. Consequently, calibrating samples from each wire spool is essential for precision. Calibration data on wire may be obtained from the manufacturer.

Computer-friendly reference functions are available for relating temperature and emf of letter-designated thermocouple types. The functions depend on thermocouple type and temperature range; they are used to generate reference tables of emf as a function of temperature, but are not well suited for calculating temperatures directly from values of emf. Approximate inverse functions are available, however, for calculating temperature and are of the form

$$t = \sum_{i=0}^{n} a_i E^i \tag{4}$$

where t = temperature, a_i = thermocouple constant coefficients, and E = voltage. Burns et al. (1992) give reference functions and approximate inverses for all letter-designated thermocouples.

The emf of a thermocouple, as measured with a high-input impedance device, is independent of the diameters of its constituent wires. Thermocouples with small-diameter wires respond faster to temperature changes and are less affected by radiation than larger ones. Large-diameter wire thermocouples, however, are necessary for high-temperature work when wire corrosion is a problem. For use in heated air or gases, thermocouples are often shielded and sometimes aspirated. One way to avoid error caused by radiation is using several thermocouples of different wire sizes and estimating the true temperature by extrapolating readings to zero diameter.

With thermocouples, temperatures can be indicated or recorded remotely on conveniently located instruments. Because thermocouples can be made of small-diameter wire, they can be used to

measure temperatures within thin materials, within narrow spaces, or in otherwise inaccessible locations.

Multiple Thermocouples

Thermocouples in series, with alternate junctions maintained at a common temperature, produce an emf that, when divided by the number of thermocouples, gives the average emf corresponding to the temperature difference between two sets of junctions. This series arrangement of thermocouples, often called a **thermopile**, is used to increase sensitivity and is often used for measuring small temperature changes and differences.

Connecting several thermocouples of the same type in parallel with a common reference junction is useful for obtaining an average temperature of an object or volume. In such measurements, however, it is important that the electrical resistances of the individual thermocouples be the same. Use of thermocouples in series and parallel arrangements is discussed in ASTM *Manual* 12.

Surface Temperature Measurement

The thermocouple is useful in determining surface temperature. It can be attached to a metal surface in several ways. For permanent installations, soldering, brazing, or peening (i.e., driving the thermocouple measuring junction into a small drilled hole) is suggested. For temporary arrangements, thermocouples can be attached by tape, adhesive, or putty-like material. For boiler or furnace surfaces, use furnace cement. To minimize the possibility of error caused by heat conduction along wires, a surface thermocouple should be made of fine wires placed in close contact with the surface being measured for about 25 mm from the junction to ensure good thermal contact. Wires must be insulated electrically from each other and from the metal surface (except at the junction).

Thermocouple Construction

Thermocouple (TC) wires are insulated with various materials, including fibrous glass, fluorocarbon resin, and ceramic insulators. Perhaps the most common insulators are polyimides or, in high-temperature applications, braided glass. At high temperatures, insulation can break down, inadvertently forming an unanticipated TC junction. In another form of thermocouple, the wires are insulated with compacted ceramic insulation inside a metal sheath, providing both mechanical protection and protection from stray electromagnetic fields. The measuring junction may be exposed or enclosed within the metal sheath. An enclosed junction may be either grounded or ungrounded to the metal sheath.

An exposed junction is in direct contact with the process stream; it is therefore subject to corrosion or contamination, but provides a fast temperature response. A grounded enclosed junction, in which the wires are welded to the metal sheath, provides electrical grounding, as well as mechanical and corrosion protection, but has a slower response time. Response time is even slower for ungrounded enclosed junctions, but the thermocouple wires are isolated electrically and are less susceptible to some forms of mechanical strain than those with grounded construction.

3.4 OPTICAL PYROMETRY

Optical pyrometry determines a surface's temperature from the color of the radiation it emits. As the temperature of a surface increases, it becomes deep red in color, then orange, and eventually white. This behavior follows from Wein's law, which indicates that the wavelength corresponding to the maximum intensity of emitted radiation is inversely proportional to the absolute temperature of the emitting surface. Thus, as temperature increases, the wavelength decreases.

To determine the unknown surface temperature, the color of radiation from the surface is optically compared to the color of a heated filament. By adjusting the current in the filament, the color of the filament is made to match the color of radiation from the source surface. When in balance, the filament virtually disappears into the background image of the surface color. Filament calibration is required to relate the filament current to the unknown surface temperature. For further information, see Holman (2001).

3.5 INFRARED RADIATION THERMOMETERS

Infrared radiation (IR) thermometers, also known as **remote temperature sensors** (Hudson 1969) or **pyrometers**, allow noncontact measurement of surface temperature over a wide range. In these instruments, radiant flux from the observed object is focused by an optical system onto an infrared detector that generates an output signal proportional to the incident radiation that can be read from a meter or display unit. Both point and scanning radiometers are available; the latter can display the temperature variation in the field of view.

IR thermometers are usually classified according to the detector used: either thermal or photon. In **thermal detectors**, a change in electrical property is caused by the heating effect of the incident radiation. Examples of thermal detectors are the thermocouple, thermopile, and metallic and semiconductor bolometers. Typical response times are one-quarter to one-half second. In **photon detectors**, a change in electrical property is caused by the surface absorption of incident photons. Because these detectors do not require an increase in temperature for activation, their response time is much shorter than that of thermal detectors. Scanning radiometers usually use photon detectors.

An IR thermometer only measures the power level of radiation incident on the detector, a combination of thermal radiation emitted by the object and surrounding background radiation reflected from the object's surface. Very accurate measurement of temperature, therefore, requires knowledge of the long-wavelength emissivity of the object as well as the effective temperature of the thermal radiation field surrounding the object. Calibration against an internal or external source of known temperature and emissivity may be needed to obtain true surface temperature from the radiation measurements.

In other cases, using published emissivity factors for common materials may suffice. Many IR thermometers have an emissivity adjustment feature that automatically calculates the effect of emissivity on temperature once the emissivity factor is entered. Thermometers that do not have an emissivity adjustment are usually preset to calculate emissivity at 0.95, a good estimate of the emissivity of most organic substances, including paint. Moreover, IR thermometers are frequently used for relative, rather than absolute, measurement; in these cases, adjustment for emissivity may be unnecessary. The most significant practical problem is measuring shiny, polished objects. Placing electrical tape or painting the measurement area with flat black paint and allowing the temperature of the tape or paint to equilibrate can mitigate this problem.

A key factor in measurement quality can be the optical resolution or spot size of the IR thermometer, because this specification determines the instrument's measurement area from a particular distance and, thus, whether a user is actually measuring the desired area. Optical resolution is expressed as distance to spot size (D:S) at the focal. Part of the D:S specification is a description of the amount of target infrared energy encircled by the spot; typically it is 95%, but may be 90%.

Temperature resolution of an IR thermometer decreases as object temperature decreases. For example, a radiometer that can resolve a temperature difference of 0.3 K on an object near 20°C may only resolve a difference of 1 K on an object at 0°C.

3.6 INFRARED THERMOGRAPHY

Infrared thermography acquires and analyzes thermal information using images from an infrared imaging system. An infrared

Licensed for single user. © 2021 ASHRAE, Inc.

imaging system consists of (1) an infrared video camera and (2) a display unit. The infrared camera scans a surface and senses the self-emitted and reflected radiation viewed from the surface. The display unit contains either a cathode-ray tube (CRT) that displays a gray-tone or color-coded thermal image of the surface or a color liquid crystal display (LCD) screen. Thermal images can also be displayed on mobile devices such as smartphones. A photograph of the image is called a **thermogram**. Introductions to infrared thermography are given by Madding (1989) and Paljak and Pettersson (1972).

Thermography has been used to detect missing insulation and air infiltration paths in building envelopes (Burch and Hunt 1978). Standard practices for conducting thermographic inspections of buildings are given in ASTM *Standard* C1060. A technique for quantitatively mapping heat loss in building envelopes is given by Mack (1986).

Aerial infrared thermography of buildings is effective in identifying regions of an individual built-up roof that have wet insulation (Tobiasson and Korhonen 1985), but it is ineffective in ranking a group of roofs according to their thermal resistance (Burch 1980; Goldstein 1978). In this latter application, the emittances of the separate roofs and outdoor climate (i.e., temperature and wind speed) throughout the microclimate often produce changes in the thermal image that may be incorrectly attributed to differences in thermal resistance.

Industrial applications include locating defective or missing pipe insulation in buried heat distribution systems, surveys of manufacturing plants to quantify energy loss from equipment, and locating defects in coatings (Bentz and Martin 1987). Madding (1989) discusses applications to electrical power systems and electronics.

4. HUMIDITY MEASUREMENT

Any instrument that can measure the humidity or psychrometric state of air is a hygrometer, and many are available. The indication sensors used on the instruments respond to different moisture property contents. These responses are related to factors such as wet-bulb temperature, relative humidity, humidity (mixing) ratio, dew point, and frost point.

Table 3 lists instruments for measuring humidity. Each is capable of accurate measurement under certain conditions and within specific limitations. The following sections describe the various instruments in more detail.

4.1 PSYCHROMETERS

A typical industrial psychrometer consists of a pair of matched electrical or mechanical temperature sensors, one of which is kept wet with a moistened wick. A blower aspirates the sensor, which lowers the temperature at the moistened temperature sensor. The lowest temperature depression occurs when the evaporation rate required to saturate the moist air adjacent to the wick is constant. This is a steady-state, open-loop, nonequilibrium process, which depends on the purity of the water, cleanliness of the wick, ventilation rate, radiation effects, size and accuracy of the temperature sensors, and transport properties of the gas.

Table 3 Humidity Sensor Properties

Type of Sensor	Sensor Category	Method of Operation	Approximate Range	Some Uses	Approximate Accuracy
Psychrometer	Evaporative cooling	Temperature measurement of wet bulb	0 to 80°C	Measurement, standard	±3 to 7% rh
Adiabatic saturation psychrometer	Evaporative cooling	Temperature measurement of thermodynamic wet bulb	5 to 30°C	Measurement, standard	±0.2 to 2% rh
Chilled mirror	Dew point	Optical determination of moisture formation	−75 to 95°C dpt	Measurement, control, meteorology	±0.2 to 2 K
Heated saturated salt solution	Water vapor pressure	Vapor pressure depression in salt solution	−30 to 70°C dpt	Measurement, control, meteorology	±1.5 K
Hair	Mechanical	Dimensional change	5 to 100% rh	Measurement, control	±5% rh
Nylon	Mechanical	Dimensional change	5 to 100% rh	Measurement, control	±5% rh
Dacron thread	Mechanical	Dimensional change	5 to 100% rh	Measurement	±7% rh
Goldbeater's skin	Mechanical	Dimensional change	5 to 100% rh	Measurement	±7% rh
Cellulosic materials	Mechanical	Dimensional change	5 to 100% rh	Measurement, control	±5% rh
Carbon	Mechanical	Dimensional change	5 to 100% rh	Measurement	±5% rh
Dunmore type	Electrical	Impedance	7 to 98% rh at 5 to 60°C	Measurement, control	±1.5% rh
Polymer film electronic hygrometer	Electrical	Impedance or capacitance	10 to 100% rh		±2 to 3% rh
Ion exchange resin	Electrical	Impedance or capacitance	10 to 100% rh at −40 to 90°C	Measurement, control	±5% rh
Porous ceramic	Electrical	Impedance or capacitance	Up to 200°C	Measurement, control	±1 to 1.5% rh
Aluminum oxide	Electrical	Capacitance	5 to 100% rh	Measurement, control	±3% rh
	Electrical	Capacitance	−80 to 60°C dpt	Trace moisture measurement, control	±1 K dpt
Electrolytic hygrometer	Electrolytic cell	Electrolyzes due to adsorbed moisture	1 to 1000 ppm	Measurement	
Infrared laser diode	Electrical	Optical diodes	0.1 to 100 ppm	Trace moisture measurement	±0.1 ppm
Surface acoustic wave	Electrical	SAW attenuation	85 to 98% rh	Measurement, control	±1% rh
Piezoelectric	Mass sensitive	Mass changes due to adsorbed moisture	−75 to −20°C	Trace moisture measurement, control	±1 to 5 K dpt
Radiation absorption	Moisture absorption	Moisture absorption of UV or IR radiation	−20 to 80°C dpt	Measurement, control, meteorology	±2 K dpt, ±5% rh
Gravimetric	Direct measurement of mixing ratio	Comparison of sample gas with dry airstream	120 to 20 000 ppm mixing ratio	Primary standard, research and laboratory	±0.13% of reading
Color change	Physical	Color changes	10 to 80% rh	Warning device	±10% rh

Notes: dpt = dew-point temperature
1. This table does not encompass all of available technology for measurement of humidity.
2. Approximate range for device types listed is based on surveys of device manufacturers.
3. Approximate accuracy is based on manufacturers' data.
4. Presently, NIST only certifies instruments with operating ranges within −75 to 100°C dpt.

Licensed for single user. © 2021 ASHRAE, Inc.

ASHRAE *Standard* 41.6 recommends an airflow over both the wet and dry bulbs of 3 to 5 m/s for transverse ventilation and 1.5 to 2.5 m/s for axial ventilation.

The **sling psychrometer** consists of two thermometers mounted side by side in a frame fitted with a handle for whirling the device through the air. The thermometers are spun until their readings become steady. In the **ventilated** or **aspirated psychrometer**, the thermometers remain stationary, and a small fan, blower, or syringe moves air across the thermometer bulbs. Various designs are used in the laboratory, and commercial models are available.

Other temperature sensors, such as thermocouples and thermistors, are also used and can be adapted for recording temperatures or for use where a small instrument is required. Small-diameter wet-bulb sensors operate with low ventilation rates.

Charts and tables showing the relationship between the temperatures and humidity are available. Data are usually based on a barometric pressure equal to one standard atmosphere. To meet special needs, charts can be produced that apply to nonstandard pressure (e.g., the ASHRAE 2250 m psychrometric chart). Alternatively, mathematical calculations can be made (Kusuda 1965). Uncertainties of 3 to 7% rh are typical for psychrometer-based derivation. The degree of uncertainty is a function of the accuracy of temperature measurements (wet- and dry-bulb), knowledge of the barometric pressure, and conformance to accepted operational procedures such as those outlined in ASHRAE *Standard* 41.6.

In air temperatures below 0°C, water on the wick may either freeze or supercool. Because the wet-bulb temperature is different for ice and water, the state must be known and the proper chart or table used. Some operators remove the wick from the wet bulb for freezing conditions and dip the bulb in water a few times; this allows water to freeze on the bulb between dips, forming a film of ice. Because the wet-bulb depression is slight at low temperatures, precise temperature readings are essential. A psychrometer can be used at high temperatures, but if the wet-bulb depression is large, the wick must remain wet and water supplied to the wick must be cooled so as not to influence the wet-bulb temperature by carrying sensible heat to it (Richardson 1965; Worrall 1965).

Greenspan and Wexler (1968) and Wentzel (1961) developed devices to measure adiabatic saturation temperature.

4.2 DEW-POINT HYGROMETERS

Condensation Dew-Point Hygrometers

The condensation (chilled-mirror) dew-point hygrometer is an accurate and reliable instrument with a wide humidity range. However, these features are gained at increased complexity and cost compared to the psychrometer. In the condensation hygrometer, a surface is cooled (thermoelectrically, mechanically, or chemically) until dew or frost begins to condense out. The condensate surface is maintained electronically in vapor-pressure equilibrium with the surrounding gas, while surface condensation is detected by optical, electrical, or nuclear techniques. The measured surface temperature is then the dew-point temperature.

The largest source of error stems from the difficulty in measuring condensate surface temperature accurately. Typical industrial versions of the instrument are accurate to ±0.5 K over wide temperature spans. With proper attention to the condensate surface temperature measuring system, errors can be reduced to about ±0.2 K. Condensation hygrometers can be made surprisingly compact using solid-state optics and thermoelectric cooling.

Wide span and minimal errors are two of the main features of this instrument. A properly designed condensation hygrometer can measure dew points from 95°C down to frost points of –75°C. Typical condensation hygrometers can cool to 80 K below ambient temperature, establishing lower limits of the instrument to dew points corresponding to approximately 0.5% rh. Accuracies for measurements above –40°C can be ±1 K or better, deteriorating to ±2 K at lower temperatures.

The response time of a condensation dew-point hygrometer is usually specified in terms of its cooling/heating rate, typically 2 K/s for thermoelectric cooled mirrors. This makes it somewhat faster than a heated salt hygrometer. Perhaps the most significant feature of the condensation hygrometer is its fundamental measuring technique, which essentially renders the instrument self-calibrating. For calibration, it is necessary only to manually override the surface cooling control loop, causing the surface to heat, and confirm that the instrument recools to the same dew point when the loop is closed. Assuming that the surface temperature measuring system is correct, this is a reasonable check on the instrument's performance.

Although condensation hygrometers can become contaminated, they can easily be cleaned and returned to service with no impairment to performance.

Salt-Phase Heated Hygrometers

Another instrument in which the temperature varies with ambient dew-point temperature is called a self-heating salt-phase transition hygrometer or a heated electrical hygrometer. This device usually consists of a tubular substrate covered by glass fiber fabric, with a spiral bifilar winding for electrodes. The surface is covered with a salt solution, usually lithium chloride. The sensor is connected in series with a ballast and a 24 V (AC) supply. When the instrument is operating, electrical current flowing through the salt film heats the sensor. The salt's electrical resistance characteristics are such that a balance is reached with the salt at a critical moisture content corresponding to a saturated solution. The sensor temperature adjusts automatically so that the water vapor pressures of the salt film and ambient atmosphere are equal.

With lithium chloride, this sensor cannot be used to measure relative humidity below approximately 12% (the equilibrium relative humidity of this salt), and it has an upper dew-point limit of about 70°C. The regions of highest precision are between –23 and 34°C, and above 40°C dew point. Another problem is that the lithium chloride solution can be washed off when exposed to water. In addition, this type of sensor is subject to contamination problems, which limits its accuracy. Its response time is also very slow: it takes approximately 2 min for a 67% step change.

4.3 MECHANICAL HYGROMETERS

Many organic materials change in dimension with changes in humidity; this action is used in a number of simple and effective humidity indicators, recorders, and controllers (see Chapter 7). They are coupled to pneumatic leak ports, mechanical linkages, or electrical transduction elements to form hygrometers.

Commonly used organic materials are human hair, nylon, Dacron, animal membrane, animal horn, wood, and paper. Their inherent nonlinearity and hysteresis must be compensated for within the hygrometer. These devices are generally unreliable below 0°C. The response is generally inadequate for monitoring a changing process, and can be affected significantly by exposure to extremes of humidity. Mechanical hygrometers require initial calibration and frequent recalibration; however, they are useful because they can be arranged to read relative humidity directly, and they are simpler and less expensive than most other types.

4.4 ELECTRICAL IMPEDANCE AND CAPACITANCE HYGROMETERS

Many substances adsorb or lose moisture with changing relative humidity and exhibit corresponding changes in electrical impedance or capacitance.

Licensed for single user. © 2021 ASHRAE, Inc.

Dunmore Hygrometers

This sensor consists of dual electrodes on a tubular or flat substrate; it is coated with a film containing salt, such as lithium chloride, in a binder to form an electrical connection between windings. The relation of sensor resistance to humidity is usually represented by graphs. Because the sensor is highly sensitive, the graphs are a series of curves, each for a given temperature, with intermediate values found by interpolation. Several resistance elements (Dunmore elements) cover a standard range. Systematic calibration is essential because the resistance grid varies with time and contamination as well as with exposure to temperature and humidity extremes.

Polymer Film Electronic Hygrometers

These devices consist of a hygroscopic organic polymer deposited by means of thin or thick film processing technology on a water-permeable substrate. Both capacitance and impedance sensors are available. The impedance devices may be either ionic or electronic conduction types. These hygrometers typically have integrated circuits that provide temperature correction and signal conditioning. The primary advantages of this sensor technology are small size; low cost; fast response times (on the order of 1 to 120 s for 64% change in relative humidity); and good accuracy over the full range, including the low end, where most other devices are less accurate.

Ion Exchange Resin Electric Hygrometers

A conventional ion exchange resin consists of a polymer with a high relative molecular mass and polar groups of positive or negative charge in cross-link structure. Associated with these polar groups are ions of opposite charge that are held by electrostatic forces to the fixed polar groups. In the presence of water or water vapor, the electrostatically held ions become mobile; thus, when a voltage is impressed across the resin, the ions are capable of electrolytic conduction. The **Pope cell** is one example of an ion exchange element. It is a wide-range sensor, typically covering 15 to 95% rh; therefore, one sensor can be used where several Dunmore elements would be required. The Pope cell, however, has a nonlinear characteristic from approximately 1000 Ω at 100% rh to several megohms at 10% rh.

Impedance-Based Porous Ceramic Electronic Hygrometers

Using oxides' adsorption characteristics, humidity-sensitive ceramic oxide devices use either ionic or electronic measurement techniques to relate adsorbed water to relative humidity. Ionic conduction is produced by dissociation of water molecules, forming surface hydroxyls. The dissociation causes proton migration, so the device's impedance decreases with increasing water content. The ceramic oxide is sandwiched between porous metal electrodes that connect the device to an impedance-measuring circuit for linearizing and signal conditioning. These sensors have excellent sensitivity, are resistant to contamination and high temperature (up to 200°C), and may get fully wet without sensor degradation. These sensors are accurate to about ±1.5% rh (±1% rh when temperature compensated) and have a moderate cost.

Aluminum Oxide Capacitive Sensor

This sensor consists of an aluminum strip that is anodized by a process that forms a porous oxide layer. A very thin coating of cracked chromium or gold is then evaporated over this structure. The aluminum base and cracked chromium or gold layer form the two electrodes of what is essentially an aluminum oxide capacitor.

Water vapor is rapidly transported through the cracked chromium or gold layer and equilibrates on the walls of the oxide pores in a manner functionally related to the vapor pressure of water in the atmosphere surrounding the sensor. The number of water molecules adsorbed on the oxide structure determines the capacitance between the two electrodes.

4.5 ELECTROLYTIC HYGROMETERS

In electrolytic hygrometers, air is passed through a tube, where moisture is adsorbed by a highly effective desiccant (usually phosphorous pentoxide) and electrolyzed. The airflow is regulated to 1.65 mL/s at a standard temperature and pressure. As the incoming water vapor is absorbed by the desiccant and electrolyzed into hydrogen and oxygen, the current of electrolysis determines the mass of water vapor entering the sensor. The flow rate of the entering gas is controlled precisely to maintain a standard sample mass flow rate into the sensor. The instrument is usually designed for use with moisture/air ratios in the range of less than 1 ppm to 1000 ppm, but can be used with higher humidities.

4.6 PIEZOELECTRIC SORPTION

This hygrometer compares the changes in frequency of two hygroscopically coated quartz crystal oscillators. As the crystal's mass changes because of absorption of water vapor, the frequency changes. The amount of water sorbed on the sensor is a function of relative humidity (i.e., partial pressure of water as well as ambient temperature).

A commercial version uses a hygroscopic polymer coating on the crystal. Humidity is measured by monitoring the change in the vibration frequency of the quartz crystal when the crystal is alternately exposed to wet and dry gas.

4.7 SPECTROSCOPIC (RADIATION ABSORPTION) HYGROMETERS

Radiation absorption devices operate on the principle that selective absorption of radiation is a function of frequency for different media. Water vapor absorbs **infrared** radiation at 2 to 3 μm wavelengths and **ultraviolet** radiation centered about the Lyman-alpha line at 0.122 μm. The amount of absorbed radiation is directly related to the absolute humidity or water vapor content in the gas mixture, according to Beer's law. The basic unit consists of an energy source and optical system for isolating wavelengths in the spectral region of interest, and a measurement system for determining the attenuation of radiant energy caused by water vapor in the optical path. Absorbed radiation is measured extremely quickly and independent of the degree of saturation of the gas mixture. Response times of 0.1 to 1 s for 90% change in moisture content are common. Spectroscopic hygrometers are primarily used where a noncontact application is required; this may include atmospheric studies, industrial drying ovens, and harsh environments. The primary disadvantages of this device are its high cost and relatively large size.

4.8 GRAVIMETRIC HYGROMETERS

Humidity levels can be measured by extracting and finding the mass of water vapor in a known quantity or atmosphere. For precise laboratory work, powerful desiccants (e.g., phosphorous pentoxide, magnesium perchlorate) are used for extraction; for other purposes, calcium chloride or silica gel is satisfactory.

When the highest level of accuracy is required, the NIST gravimetric hygrometer is recommended. The gravimetric hygrometer gives the absolute water vapor content, where the mass of absorbed water and precise measurement of the gas volume associated with the water vapor determine the mixing ratio or absolute humidity of the sample. This system is the primary standard because the required measurements of mass, temperature, pressure, and volume can be made with extreme precision. However, its complexity and required attention to detail limit its usefulness. See Meyer et al. (2010) for further information.

Licensed for single user. © 2021 ASHRAE, Inc.

4.9 CALIBRATION

For many hygrometers, the need for recalibration depends on the accuracy required, the sensor's stability, and the conditions to which the sensor is subjected. Many hygrometers should be calibrated regularly by exposure to an atmosphere maintained at a known humidity and temperature, or by comparison with a transfer standard hygrometer. Complete calibration usually requires observation of a series of temperatures and humidities. Methods for producing known humidities include saturated salt solutions (Greenspan 1977); sulfuric acid solutions; and mechanical systems, such as the divided flow, two-pressure (Amdur 1965); two-temperature (Till and Handegord 1960); and NIST two-pressure humidity generator (Hasegawa 1976). All these systems rely on precise methods of temperature and pressure control in a controlled environment to produce a known humidity, usually with accuracies of 0.5 to 1.0%. The operating range for the precision generator is typically 5 to 95% rh.

5. PRESSURE MEASUREMENT

Pressure is the force exerted per unit area by a medium, generally a liquid or gas. Pressure so defined is sometimes called **absolute pressure**. Thermodynamic and material properties are expressed in terms of absolute pressures; thus, the properties of a refrigerant are given in terms of absolute pressures. **Vacuum** refers to pressures below atmospheric.

Differential pressure is the difference between two absolute pressures, or the difference between two relative pressures measured with respect to the same reference pressure. Often, it can be very small compared to either of the absolute pressures (these are often referred to as low-range, high-line differential pressures). A common example of differential pressure is the pressure drop, or difference between inlet and outlet pressures, across a filter or flow element.

Gage pressure is a special case of differential pressure where the reference pressure is atmospheric pressure. Many pressure gages, including most refrigeration test sets, are designed to make gage pressure measurements, and there are probably more gage pressure measurements made than any other. Gage pressure measurements are often used as surrogates for absolute pressures. However, because of variations in atmospheric pressure caused by elevation (e.g., atmospheric pressure in Denver, Colorado, is about 81% of sea-level pressure) and weather changes, using gage pressures to determine absolute pressures can significantly restrict the accuracy of the measured pressure, unless corrections are made for the local atmospheric pressure at the time of measurement.

Pressures can be further classified as static or dynamic. **Static pressures** have a small or undetectable change with time; **dynamic pressures** include a significant pulsed, oscillatory, or other time-dependent component. Static pressure measurements are the most common, but equipment such as blowers and compressors can generate significant oscillatory pressures at discrete frequencies. Flow in pipes and ducts can generate resonant pressure changes, as well as turbulent "noise" that can span a wide range of frequencies.

Units

A plethora of pressure units, many of them poorly defined, are in common use. The international (SI) unit is the newton per square metre, called the pascal (Pa). Although the bar and standard atmosphere are used, they should not be introduced where they are not used at present.

5.1 INSTRUMENTS

Broadly speaking, pressure instruments can be divided into three different categories: standards, mechanical gages, and electromechanical transducers. Standards instruments are used for the most accurate calibrations. The liquid-column manometer, which is the most common and potentially the most accurate standard, is used for a variety of applications, including field applications. Mechanical pressure gages are generally the least expensive and the most common. However, electromechanical transducers have become much less expensive and are easier to use, so they are being used more often.

Pressure Standards

Liquid-column manometers measure pressure by determining the vertical displacement of a liquid of known density in a known gravitational field. Typically, they are constructed as a U-tube of transparent material (glass or plastic). The pressure to be measured is applied to one side of the U-tube. If the other (reference) side is evacuated (zero pressure), the manometer measures absolute pressure; if the reference side is open to the atmosphere, it measures gage pressure; if the reference side is connected to some other pressure, the manometer measures the differential between the two pressures. Manometers filled with water and different oils are often used to measure low-range differential pressures. In some low-range instruments, one tube of the manometer is inclined to enhance readability. Mercury-filled manometers are used for higher-range differential and absolute pressure measurements. In the latter case, the reference side is evacuated, generally with a mechanical vacuum pump. Typical full-scale ranges for manometers vary from 25 Pa to 300 kPa.

For pressures above the range of manometers, standards are generally of the piston-gage, pressure-balance, or deadweight-tester type. These instruments apply pressure to the bottom of a vertical piston, which is surrounded by a close-fitting cylinder (typical clearances are micrometres). The pressure generates a force approximately equal to the pressure times the area of the piston. This force is balanced by weights stacked on the top of the piston. If the mass of the weights, local acceleration of gravity, and area of the piston (or more properly, the "effective area" of the piston and cylinder assembly) are known, the applied pressure can be calculated. Piston gages usually generate gage pressures with respect to the atmospheric pressure above the piston. They can be used to measure absolute pressures either indirectly, by separately measuring the atmospheric pressure and adding it to the gage pressure determined by the piston gage, or directly, by surrounding the top of the piston and weights with an evacuated bell jar. Piston gage full-scale ranges vary from 35 kPa to 1.4 GPa.

At very low absolute pressures (below about 100 Pa), a number of different types of standards are used. These tend to be specialized and expensive instruments found only in major standards laboratories. However, one low-pressure standard, the **McLeod gage**, has been used for field applications. Unfortunately, although its theory is simple and straightforward, it is difficult to use accurately, and major errors can occur when it is used to measure gases that condense or are adsorbed (e.g., water). In general, other gages should be used for most low-pressure or vacuum applications.

Mechanical Pressure Gages

Mechanical pressure gages couple a pressure sensor to a mechanical readout, typically a pointer and dial. The most common type uses a **Bourdon tube** sensor, which is essentially a coiled metal tube of circular or elliptical cross section. Increasing pressure applied to the inside of the tube causes it to uncoil. A mechanical linkage translates the motion of the end of the tube to the rotation of a pointer. In most cases, the Bourdon tube is surrounded by atmospheric pressure, so that the gages measure gage pressure. A few instruments surround the Bourdon tube with a sealed enclosure that can be evacuated for absolute measurements or connected to another pressure for differential measurements. Available instruments vary widely in cost, size, pressure range, and accuracy. Full-scale ranges can vary

Licensed for single user. © 2021 ASHRAE, Inc.

from 35 kPa to 700 MPa. Accuracy of properly calibrated and used instruments can vary from 0.1 to 10% of full scale. Generally there is a strong correlation between size, accuracy, and price; larger instruments are more accurate and expensive.

For better sensitivity, some low-range mechanical gages (sometimes called **aneroid gages**) use corrugated diaphragms or capsules as sensors. The capsule is basically a short bellows sealed with end caps. These sensors are more compliant than a Bourdon tube, and a given applied pressure causes a larger deflection of the sensor. The inside of a capsule can be evacuated and sealed to measure absolute pressures or connected to an external fitting to allow differential pressures to be measured. Typically, these gages are used for low-range measurements of 100 kPa or less. In better-quality instruments, accuracies can be 0.1% of reading or better.

Electromechanical Transducers

Mechanical pressure gages are generally limited by inelastic behavior of the sensing element, friction in the readout mechanism, and limited resolution of the pointer and dial. These effects can be eliminated or reduced by using electronic techniques to sense the distortion or stress of a mechanical sensing element and electronically convert that stress or distortion to a pressure reading. Various sensors are used, including Bourdon tubes, capsules, diaphragms, and different resonant structures whose vibration frequency varies with the applied pressure. Capacitive, inductive, and optical lever sensors are used to measure the sensor element's displacement. In some cases, feedback techniques may be used to constrain the sensor in a null position, minimizing distortion and hysteresis of the sensing element. Temperature control or compensation is often included. Readout may be in the form of a digital display, analog voltage or current, or a digital code. Size varies, but for transducers using a diaphragm fabricated as part of a silicon chip, the sensor and signal-conditioning electronics can be contained in a small transistor package, and the largest part of the device is the pressure fitting. The best of these instruments achieve long-term instabilities of 0.01% or less of full scale, and corresponding accuracies when properly calibrated. Performance of less-expensive instruments can be more on the order of several percent.

Although the dynamic response of most mechanical gages is limited by the sensor and readout, the response of some electromechanical transducers can be much faster, allowing measurements of dynamic pressures at frequencies up to 1 kHz and beyond in the case of transducers specifically designed for dynamic measurements. Consult manufacturers' literature as a guide to the dynamic response of specific instruments.

As the measured pressure drops below about 10 kPa, it becomes increasingly difficult to sense mechanically. Various gages have been developed that measure some other property of the gas that is related to the pressure. In particular, **thermal conductivity gages**, also known as **thermocouple**, **thermistor**, **Pirani**, and **convection gages**, are used for pressures down to about 0.1 Pa. These gages have a sensor tube with a small heated element and a temperature sensor; the temperature of the heated element is determined by the thermal conductivity of the gas, and the output of the temperature sensor is displayed on an analog or digital electrical meter contained in an attached electronics unit. The accuracy of thermal conductivity gages is limited by their nonlinearity, dependence on gas species, and tendency to read high when contaminated. Oil contamination is a particular problem. However, these gages are small, reasonably rugged, and relatively inexpensive; in the hands of a typical user, they give far more reliable results than a McLeod gage. They can be used to check the base pressure in a system that is being evacuated before being filled with refrigerant. They should be checked periodically for contamination by comparing the reading with that from a new, clean sensor tube.

General Considerations

Accurate values of atmospheric or barometric pressure are required for weather prediction and aircraft altimetry. In the United States, the National Weather Service, Federal Aviation Administration, and local airport operating authorities maintain a network of calibrated instruments, generally accurate to within 0.1% of reading and located at airports. These agencies are usually cooperative in providing current values of atmospheric pressure that can be used to check the calibration of absolute pressure gages or to correct gage pressure readings to absolute pressures. However, pressure readings generally reported for weather and altimetry purposes are not the true atmospheric pressure, but rather a value adjusted to an equivalent sea-level pressure. Therefore, unless the location is near sea level, it is important to ask for the station or true atmospheric pressure rather than using the adjusted values broadcast by radio stations. Further, atmospheric pressure decreases with increasing elevation at a rate (near sea level) of about 10 Pa/m, and corresponding corrections should be made to account for the difference in elevation between the instruments being compared.

Gage-pressure instruments are sometimes used to measure absolute pressures, but their accuracy can be compromised by uncertainties in atmospheric pressure. This error can be particularly serious when gage-pressure instruments are used to measure vacuum (negative gage pressures). For all but the crudest measurements, absolute-pressure gages should be used for vacuum measurements; for pressures below about 100 Pa, a thermal conductivity gage should be used.

All pressure gages are susceptible to temperature errors. Several techniques are used to minimize these errors: sensor materials are generally chosen to minimize temperature effects, mechanical readouts can include temperature compensation elements, electromechanical transducers may include a temperature sensor and compensation circuit, and some transducers operate at a controlled temperature. Clearly, temperature effects are of greater concern for field applications, and it is prudent to check the manufacturers' literature for the temperature range over which the specified accuracy can be maintained. Abrupt temperature changes can also cause large transient errors that may take some time to decay.

Readings of some electromechanical transducers with a resonant or vibrating sensor can depend on the gas species. Although some of these units can achieve calibrated accuracies of the order of 0.01% of reading, they are typically calibrated with dry air or nitrogen, and readings for other gases can be in error by several percent, possibly much more for refrigerants and other high-density gases. High-accuracy readings can be maintained by calibrating these devices with the gas to be measured. Consult manufacturers' literature.

Measuring dynamic pressures is limited not just by the frequency response of the pressure gage, but also by the hydraulic or pneumatic time constant of the connection between the gage and the system to be monitored. Generally, the longer the connecting lines and the smaller their diameter, the lower the system's frequency response. Further, even if only the static component of the pressure is of interest, and a gage with a low-frequency response is used, a significant pulsating or oscillating pressure component can cause significant errors in pressure gage readings and, in some cases, can damage the gage, particularly one with a mechanical readout mechanism. In these cases, a filter or snubber should be used to reduce the higher-frequency components.

6. AIR VELOCITY MEASUREMENT

HVAC engineers measure the flow of air more often than any other gas, and usually at or near atmospheric pressure. Under this condition, air can be treated as an incompressible (i.e., constant-density) fluid, and simple formulas give sufficient precision to solve

Licensed for single user. © 2021 ASHRAE, Inc.

many problems. Instruments that measure fluid velocity and their application range and precision are listed in Table 4.

6.1 AIRBORNE TRACER TECHNIQUES

Tracer techniques are suitable for measuring velocity in an open space. Typical tracers include smoke, feathers, pieces of lint, and radioactive or nonradioactive gases. Measurements are made by timing the rate of movement of solid tracers or by monitoring the change in concentration level of gas tracers.

Smoke is a useful qualitative tool in studying air movements. Smoke can be obtained from titanium tetrachloride (irritating to nasal membranes) or by mixing potassium chlorate and powdered sugar (nonirritating) and firing the mixture with a match. The latter process produces considerable heat and should be confined to a pan away from flammable materials. Titanium tetrachloride smoke works well for spot tests, particularly for leakage through casings and ducts, because it can be handled easily in a small, pistol-like ejector. Another alternative is theatrical smoke, which is nontoxic, but requires proper illumination.

Fumes of ammonia water and sulfuric acid, if allowed to mix, form a white precipitate. Two bottles, one containing ammonia water and the other containing acid, are connected to a common nozzle by rubber tubing. A syringe forces air over the liquid surfaces in the bottles; the two streams mix at the nozzle and form a white cloud.

A satisfactory test smoke also can be made by bubbling an airstream through ammonium hydroxide and then hydrochloric acid (Nottage et al. 1952). Smoke tubes, smoke candles, and smoke bombs are available for studying airflow patterns.

6.2 ANEMOMETERS

Deflecting Vane Anemometers

The deflecting vane anemometer consists of a pivoted vane enclosed in a case. Air exerts pressure on the vane as it passes through the instrument from an upstream to a downstream opening. A hair spring and a damping magnet resist vane movement. The instrument gives instantaneous readings of directional velocities on an indicating scale. With fluctuating velocities, needle swings must be visually averaged. This instrument is useful for studying air motion in a room, locating objectionable drafts, measuring air velocities at supply and return diffusers and grilles, and measuring laboratory hood face velocities.

Propeller or Revolving (Rotating) Vane Anemometers

The propeller anemometer consists of a light, revolving, wind-driven wheel connected through a gear train to a set of recording dials that read linear metres of air passing in a measured length of time. It is made in various sizes, though 75, 100, and 150 mm are the most common. Each instrument requires individual calibration. At low velocities, the mechanism's friction drag is considerable, and is usually compensated for by a gear train that overspeeds. For this reason, the correction is often additive at the lower range and subtractive at the upper range, with the least correction in the middle range. The best instruments have starting speeds of 0.25 m/s or higher; therefore, they cannot be used below that air speed. Electronic revolving vane anemometers, with optical or magnetic pick-ups to sense the rotation of the vane, are available in vane sizes as small as 13 mm.

Cup Anemometers

The cup anemometer is primarily used to measure outdoor, meteorological wind speeds. It consists of three or four hemispherical cups mounted radially from a vertical shaft. Wind from any direction with a vector component in the plane of cup rotation causes the cups and shaft to rotate. Because it is primarily used to measure meteorological wind speeds, the instrument is usually constructed so that wind speeds can be recorded or indicated electrically at a remote point.

Thermal Anemometers

The thermal (or hot-wire, or hot-film) anemometer consists of a heated RTD, thermocouple junction, or thermistor sensor constructed at the end of a probe; it is designed to provide a direct, simple method of determining air velocity at a point in the flow field. The probe is placed into an airstream, and air movement past the electrically heated velocity sensor tends to cool the sensor in proportion to the speed of the airflow. The electronics and sensor are commonly combined into a portable, hand-held device that interprets the sensor signal and provides a direct reading of air velocity in either analog or digital display format. Often, the sensor probe also incorporates an ambient temperature-sensing RTD or thermistor, in which case the indicated air velocity is temperature compensated to standard air density conditions (typically 1.20 kg/m^3).

Thermal anemometers have long been used in fluid flow research. Research anemometer sensors have been constructed using very fine wires in configurations that allow characterization of fluid flows in one, two, and three dimensions, with sensor/electronics response rates up to several hundred kilohertz. This technology has been incorporated into more ruggedized sensors suitable for measurements in the HVAC field, primarily for unidirectional airflow measurement. Omnidirectional sensing instruments suitable for thermal comfort studies are also available.

The principal advantages of thermal anemometers are their wide dynamic range and their ability to sense extremely low velocities. Commercially available portable instruments often have a typical accuracy (including repeatability) of 2 to 5% of reading over the entire velocity range. Accuracies of ±2% of reading or better are obtainable from microcontroller (microprocessor)-based thermistor and RTD sensor assemblies, some of which can be factory-calibrated to known reference standards (e.g., NIST air speed tunnels). An integrated microcontroller also allows an array of sensor assemblies to be combined in one duct or opening, providing independently derived velocity and temperature measurements at each point.

Limitations of thermistor-based velocity measuring devices depend on sensor configuration, specific thermistor type used, and the application. At low velocities, thermal anemometers can be significantly affected by their own thermal plumes (from self heating). Products using this technology can be classified as hand-held instruments or permanently mounted probes and arrays, and as those with analog electronic transmitters and those that are microcontroller-based.

Limitations of hand-held and analog electronic thermal anemometers include the following: (1) the unidirectional sensor must be carefully aligned in the airstream (typically to within ±20° rotation) to achieve accurate results; (2) the velocity sensor must be kept clean because contaminant build-up can change the calibration (which may change accuracy performance); and (3) because of the inherent high speed of response of thermal anemometers, measurements in turbulent flows can yield fluctuating velocity measurements. Electronically controlled time-integrated functions are now available in many digital air velocity meters to help smooth these turbulent flow measurements.

Microcontroller-based thermal dispersion devices are typically configured as unidirectional instruments, but may have multiple velocity-sensing elements capable of detecting flow direction. These devices can be used to measure a "bleed" air velocity between two spaces or across a fixed orifice. With mathematical conversion, these measured velocities can closely approximate equivalents in differential pressure down to two decimal places (Pa). They can be used for space pressure control, to identify minute changes in flow

Table 4 Air Velocity Measurement

Measurement Means	Application	Range, m/s	Precision	Limitations
Smoke puff or airborne solid tracer	Low air velocities in rooms; highly directional	0.025 to 0.25	10 to 20%	Awkward to use but valuable in tracing air movement.
Deflecting vane anemometer	Air velocities in rooms, at outlets, etc.; directional	0.15 to 120	5%	Requires periodic calibration check.
Revolving (rotating) vane anemometer	Moderate air velocities in ducts and rooms; somewhat directional	0.5 to 15	2 to 5%	Subject to significant errors when variations in velocities with space or time are present. Easily damaged. Affected by turbulence intensity. Requires periodic calibration.
Thermal (hot-wire or hot-film) anemometer	a. Low air velocities; directional and omnidirectional available b. Transient velocity and turbulence	0.05 to 50	2 to 10%	Requires accurate calibration at frequent intervals. Some are relatively costly. Affected by thermal plume because of self-heating.
Pitot-static tube	Standard (typically hand-held) instrument for measuring single-point duct velocities	0.9 to 50 with micromanometer; 3 to 50 with draft gages; 50 up with manometer	2 to 5%	Accuracy falls off at low end of range because of square-root relationship between velocity and dynamic pressure. Also affected by alignment with flow direction.
Impact tube and sidewall or other static tap	High velocities, small tubes, and where air direction may be variable	0.6 to 50 with micromanometer; 3 to 50 with draft gages; 50 up with manometer	2 to 5%	Accuracy depends on constancy of static pressure across stream section.
Cup anemometer	Meteorological	Up to 60	2 to 5%	Poor accuracy at low air velocity (<2.5 m/s).
Ultrasonic	Large instruments: meteorological Small instruments: in-duct and room air velocities	0.005 to 30	1 to 2%	High cost.
Laser Doppler velocimeter (LDV)	Calibration of air velocity instruments	0.005 to 30	1 to 3%	High cost and complexity limit LDVs to laboratory applications. Requires seeding of flow with particles, and transparent optical access (window).
Particle image velocimetry (PIV)	Full-field (2D, 3D) velocity measurements in rooms, outlets	0.005 to 30	10%	High cost and complexity limits measurements to laboratory applications. Requires seeding of flow with particles, and transparent optical access (window).
Pitot array, self-averaging differential pressure, typically using equalizing manifolds	In duct assemblies, ducted or fan inlet probes	3 to 50	±2 to >40% of reading	Performance depends heavily on quality and range of associated differential pressure transmitter. Very susceptible to measurement errors caused by duct placement and temperature changes. Nonlinear output (square-root function). Mathematical averaging errors likely because of sampling method. Must be kept clean to function properly. Must be set up and field calibrated to hand-held reference, or calibrated against nozzle standard.
Piezometer and piezoring variations, self-averaging differential pressure using equalizing manifolds	Centrifugal fan inlet cone	3 to 50	±5 to >40% of reading	Performance depends heavily on quality and range of required differential pressure transmitter. Very susceptible to measurement errors caused by inlet cone placement, inlet obstructions, and temperature changes. Nonlinear output (square-root function). Must be kept clean. Must be field calibrated to hand-held reference.
Vortex shedding	In-duct assemblies, ducted or fan inlet probes	2 to 30	±2.5 to 10% of reading	Highest cost per sensing point. Largest physical size. Low-temperature accuracy questionable. Must be set up and field calibrated to hand-held reference.
Thermal (analog electronic) using thermistors	In-duct assemblies or ducted probes	0.25 to 25	±2 to 40% of reading	Mathematical averaging errors may be caused by analog electronic circuitry when averaging nonlinear signals. Sensing points may not be independent. May not be able to compensate for temperatures beyond a narrow range. Must be set up and field calibrated to hand-held reference. Must be recalibrated regularly to counteract drift.
Drag force	In-duct flow	0.1 to 50	±2%	Piezoelectric or strain-gage methods are used to sense dynamic drag-force variations.
Thermal dispersion (microcontroller-based) using thermistors to independently determine temperatures and velocities	Ducted or fan inlet probes, bleed velocity sensors	0.1 to 50	±2 to 10% of reading	Cost increases with number of sensor assemblies in array. Honeycomb air straighteners are recommended by some manufacturers. Accuracy verified only to –29°C. Not suitable for abrasive or high-temperature environments.
Thermal (analog electronic) using RTDs	In-duct assemblies or ducted probes; stainless steel and platinum RTDs have industrial environment capabilities	0.5 to 90	±1 to 20% of reading	Requires long duct/pipe runs. Sensitive to placement conditions. Mathematical averaging errors may be caused by analog electronic circuitry when averaging nonlinear signals. Must be recalibrated regularly to counteract drift. Fairly expensive.

Licensed for single user. © 2021 ASHRAE, Inc.

direction, or for estimating volumetric flow rates across a fixed orifice by equating to velocity pressure.

Thermal anemometers are suitable for a variety of HVAC applications. They are particularly well suited to the low velocities associated with outdoor air intake measurement and control, return or relief fan tracking for pressurization in variable-air-volume (VAV) systems, VAV terminal box measurement, unit ventilator and packaged equipment intake measurement, space pressurization for medical isolation, and laboratory fume hood face velocity measurements (typically in the 0.25 to 1 m/s range). Thermal anemometers can also take multipoint traverse measurements in ventilation ductwork.

Laser Doppler Velocimeters (or Anemometers)

The laser Doppler velocimeter (LDV) or laser Doppler anemometer (LDA) is an extremely complex system that collects scattered light produced by particles (i.e., seed) passing through the intersection volume of two intersecting laser beams of the same light frequency, which produces a regularly spaced fringe pattern (Mease et al. 1992). The scattered light consists of bursts containing regularly spaced oscillations whose frequency is linearly proportional to the speed of the particle. Because of their cost and complexity, they are usually not suitable for in situ field measurements. Rather, the primary HVAC application of LDV systems is calibrating systems used to calibrate other air velocity instruments.

The greatest advantage of an LDV is its performance at low air speeds: as low as 0.075 m/s with uncertainty levels of 1% or less (Mease et al. 1992). In addition, it is nonintrusive in the flow; only optical access is required. It can be used to measure fluctuating components as well as mean speeds and is available in one-, two-, and even three-dimensional configurations. Its biggest disadvantages are its high cost and extreme technological complexity, which requires highly skilled operators. Modern fiber-optic systems require less operator skill but at a considerable increase in cost.

Particle Image Velocimetry (PIV)

Particle image velocimetry (PIV) is an optical method that measures fluid velocity by determining the displacement of approximately neutrally buoyant seed particles introduced in the flow. Particle displacements are determined from images of particle positions at two instants of time. Usually, statistical (correlation) methods are used to identify the displacement field.

The greatest advantage of PIV is its ability to examine two- and three-dimensional velocity fields over a region of flow. The method usually requires laser light (sheet) illumination, and is typically limited to a field area of less than 1 m^2. Accuracy is usually limited to about ±10% by the resolution of particle displacements, which must be small enough to remain in the field of view during the selected displacement time interval. For more comprehensive information on PIV, including estimates of uncertainty, see Raffel et al. (1998).

6.3 PITOT-STATIC TUBES

The pitot-static tube, in conjunction with a suitable manometer or differential pressure transducer, provides a simple method of determining air velocity at a point in a flow field. Figure 6 shows the construction of a standard pitot tube (ASHRAE *Standard* 51) and the method of connecting it with inclined manometers to display both static pressure and velocity pressure. The equation for determining air velocity from measured velocity pressure is

$$V = \sqrt{\frac{2p_w}{\rho}} \tag{5}$$

where

V = velocity, m/s
p_w = velocity pressure (pitot-tube manometer reading), Pa
ρ = density of air, kg/m^3

The type of manometer or differential pressure transducer used with a pitot-static tube depends on the magnitude of velocity pressure being measured and on the desired accuracy. Over 7.5 m/s, a draft gage of appropriate range is usually satisfactory. If the pitot-static tube is used to measure air velocities lower than 7.5 m/s, a precision manometer or comparable pressure differential transducer is essential.

Example 1.

Step 1. Numerical evaluation. Let $p_w = 93.16 \pm 0.95$ Pa and $\rho = 1.185 \pm 0.020$ kg/m^3. Then,

$$V = \sqrt{\frac{2p_w}{\rho}} = \sqrt{\frac{2(93.16)}{(1.185)}} = 12.54 \text{ m/s}$$

Step 2. Uncertainty estimate. Let the typical bias (i.e., calibration) uncertainty of the pitot tube be $u_{V,bias} = \pm 1\%$ of reading. The uncertainty in the velocity measurement is thus estimated to be

$$\begin{aligned} u_V &= \sqrt{(u_{V,bias})^2 + (u_{V,prec})^2} \\ &= \sqrt{(u_{V,bias})^2 + \left[\frac{1}{2}(u_{pw})\right]^2 + \left[\frac{1}{2}(u_\rho)\right]^2} \\ &= \sqrt{(0.01)^2 + \left[\frac{1}{2}\left(\frac{0.95}{93.16}\right)\right]^2 + \left[\frac{1}{2}\left(\frac{0.020}{1.185}\right)\right]^2} \\ &= \pm 0.014 = \pm 1.4\% \end{aligned}$$

Therefore,

$$U_V = \pm u_V V = \pm(0.014)(12.54 \text{ m/s}) = \pm 0.18 \text{ m/s}$$

In summary,

$$V = 12.54 \pm 0.18 \text{ m/s}$$

Other pitot-static tubes have been used and calibrated. To meet special conditions, various sizes of pitot-static tubes geometrically similar to the standard tube can be used. For relatively high velocities in ducts of small cross-sectional area, total pressure readings can be obtained with an impact (pitot) tube. Where static pressure across the stream is relatively constant, as in turbulent flow in a straight duct, a sidewall tap to obtain static pressure can be used with the impact tube to obtain the velocity pressure. One form of impact tube is a small streamlined tube with a fine hole in its upstream end and its axis parallel to the stream.

(A) PITOT-STATIC PROBE WIND TUNNEL SETUP

(B) PROBE PRESSURE COEFFICIENT

Fig. 7 Pitot-Static Probe Pressure Coefficient Yaw Angular Dependence

Licensed for single user. © 2021 ASHRAE, Inc.

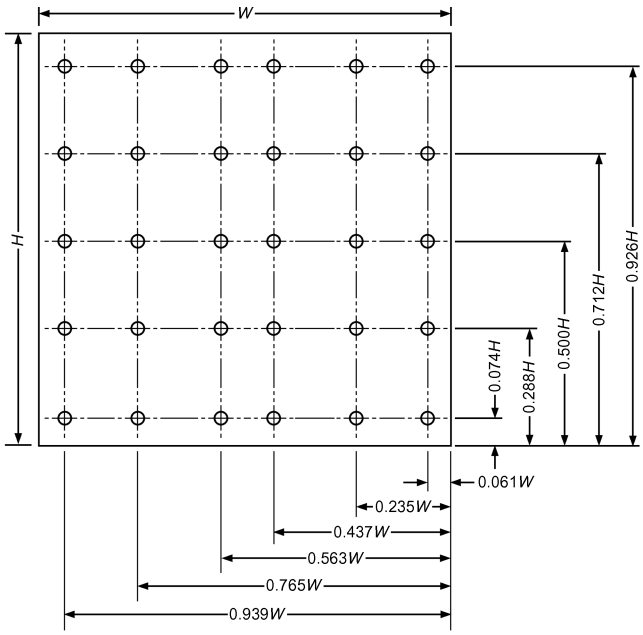
If the Mach number of the flow is greater than about 0.3, the effects of compressibility should be included in the computation of the air speed from pitot-static and impact (stagnation or pitot) tube measurements (Mease et al. 1992).

It is extremely important to recognize that the pitot-static probe is designed to make measurements when aligned with the flow. Misalignment in yaw angle of up to about 15 to 20° generally do not result in large errors; however, for greater angles, errors can be very large. For large misalignment with flow, the total pressure port of a pitot-static probe does not measure the true total (or stagnation) pressure, and the static pressure ports likewise do not measure the true static pressure of the flow stream. The error in the probe can be represented as a function of tilt (yaw or pitch) angle θ in terms of a pressure coefficient defined as follows:

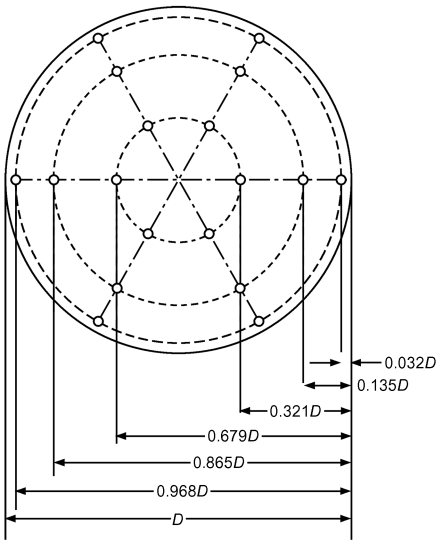
$$C_p(\theta) \equiv \frac{p_{total}(\theta) - p_{static}(\theta)}{p_{total}(0°) - p_{static}(0°)} \quad (6)$$

where $p_{total}(\theta)$ is the pressure registered at the total pressure port (see Figures 6 and 7A), and $p_{static}(\theta)$ is the pressure registered at the static pressure port (see Figure 6) at tilt angle θ. Note that, at a tilt angle of 0°, the probe is correctly aligned with flow and the total pressure and static pressure are correctly registered at each of the corresponding ports.

Figure 7B shows the typical yaw (or pitch) angle dependence of a pitot-static probe subjected to a uniform velocity field U in a wind tunnel, as shown in Figure 7A. The polar plot shows the variation of pressure coefficient $C_p(\theta)$ with yaw (or pitch) angle over the entire 360° range (essentially a symmetrical ±180 degrees). A pressure coefficient of $C_p = 1$ corresponds to a situation of good alignment with the flow and thus negligible error. Note that the pressure coefficient varies from +1 to –1 over the entire range of yaw (or pitch) angles. In reverse flows (θ near 180°), output hovers around zero flow coefficient. Because the pitot-static probe does not provide a flow direction indication, it is not possible to determine the particular region of yaw (or pitch) angle operation. Therefore, the correct output for assessing volumetric flow rate (where it is desired to measure the axial flow component) cannot be determined with confidence (Hickman et al. 2012, 2015a, 2015b).



6.4 MEASURING FLOW IN DUCTS



Because velocity in a duct is seldom uniform across any section, and a pitot tube reading or thermal anemometer indicates velocity at only one location, a traverse is usually made to determine average velocity. Generally, velocity is lowest near the side-wall edges or corners and greatest at or near the center of a duct.

To determine velocity in a traverse plane, a straight average of individual point velocities gives satisfactory results when point velocities are determined by the **log-Tchebycheff (log-T) rule** or, if care is taken, by the **equal-area method**. Figure 8 shows suggested sensor locations for traversing round and rectangular ducts. The log-Tchebycheff rule provides the greatest accuracy because its location of traverse points accounts for the effect of wall friction and the fall-off of velocity near wall ducts. For single-path disturbances (straight ducts, transitions, and elbow fittings), the equal-area method has been shown to give a consistent 3 to 4% positive bias, regardless of probe type (pitot-static, hot-wire anemometer), volumetric flow rate, or traverse location within 7.5 equivalent diameters downstream of a fitting disturbance (Hickman et al. 2012, 2015a, 2015b). The log-T method is now recommended for rectangular ducts with H and W > 460 mm. For circular ducts, the log-T and log-linear methods are similar. Log-T minimizes the positive error (measured greater than actual) caused by the failure to account for losses at the duct wall. This error can occur when using the older method of equal subareas to traverse rectangular ducts. The equal-area method is perhaps easier to implement, because it does not require nonuniform measurement grid spacing and generally specifies fewer measurement locations. Therefore, it seems reasonable to first assess the volumetric flow rate with equal area method and subsequently reduce the indicated result by approximately 3 to 4%, thereby achieving a good approximation of the log-T traverse measurement. This may be a reasonable compromise for those who do not wish to use the log-T method (Hickman et al. 2012).

When using the log-T method for a rectangular duct traverse, measure a minimum of 25 points. For a circular duct traverse, the log-linear rule and three symmetrically disposed diameters may be used (Figure 8). Points on two perpendicular diameters may be used where access is limited.

If possible, measuring points should be located at least 7.5 hydraulic diameters downstream and 3 hydraulic diameters upstream

Duct Dimensions	No. of Points for Traverse Lines	Position Relative to Inner Wall
460 mm < *H*, *W* < 750 mm	5	0.074, 0.288, 0.500, 0.712, 0.926
750 mm ≤ *H*, *W* ≤ 900 mm	6	0.061, 0.235, 0.437, 0.563, 0.765, 0.939
H, *W* > 900 mm	7	0.053, 0.203, 0.366, 0.500, 0.634, 0.797, 0.947

Log-Tchebycheff Rule for Rectangular Ducts

No. of Measuring Points per Diameter	Position Relative to Inner Wall
6	0.032, 0.135, 0.321, 0.679, 0.865, 0.968
8	0.021, 0.117, 0.184, 0.345, 0.655, 0.816, 0.883, 0.979
10	0.019, 0.077, 0.153, 0.217, 0.361, 0.639, 0.783, 0.847, 0.923, 0.981

Log-Linear Rule for Circular Ducts

Note: Example duct has 5 × 6 (*H* × *W*) measurement pattern, as for rectangular duct of 600 × 750 mm.

Fig. 8 Measuring Points for Rectangular and Round Duct Traverse

from a disturbance (e.g., caused by a turn). However, for common single-path rectangular duct fitting disturbances (60° and 90° transitions, 90° elbows), measurements can be made to uncertainties within about ±3 to 4% for traverses even as close as 1 to 2 equivalent diameters downstream of the disturbance using the log-T traverse method. Furthermore, similar results can be obtained in single-path rectangular ducts with these types disturbances using either a pitot-static probe or a hot-wire anemometer (Hickman et al. 2012).

Because field-measured airflows are rarely steady and uniform, particularly near disturbances, accuracy can be improved by increasing the number of measuring points. Straightening vanes (ASHRAE *Standard* 51) located 1.5 duct diameters ahead of the traverse plane improve measurement precision.

When velocities at a traverse plane fluctuate, the readings should be averaged on a time-weighted basis. Two traverse readings in short succession also help to average out velocity variations that occur with time. If negative velocity pressure readings are encountered, this is an indication that highly nonuniform flows are present. From the characteristics of the pitot-static probe yaw variation shown in Figure 7, it is not possible to draw meaningful and reliable conclusions from the measurements, particularly downstream of tee fitting disturbances, where boundary layer separation occurs (which causes flow reversal) in the branch region downstream of the tee. Even if no actual reversal occurs, the flow may also be highly nonaxial, and the flow directional limitations of the pitot-static probe, as shown in Figure 7B, may still result in meaningless results. Also, it is important to note that, although the pitot-static probe can produce a negative and potentially meaningless output, it does indicate obvious flow uniformity problems. *Important Note*: negative velocity pressures measured by a pitot-static tube indicate an unacceptable traverse location. To achieve meaningful volumetric flow rate measurements, traverses must be performed where no negative velocity pressure values occur. The presence of negative velocity pressures (even when those values are considered to be zero-velocity values when summing and averaging) results in a completely meaningless duct flow calculation.

A hot-wire anemometer cannot indicate flow direction. Consequently, it always indicates a positive velocity, even under reverse flow. Hence, use of a thermal anemometer probe wherever flow reversals occur, such as those encountered in the downstream branch of tee fittings, can result in large errors. For traverse measurements in the downstream branch of tees, regions of apparent negative velocity pressure have been encountered as far as 7.5 equivalent diameters downstream of the tee, and are more likely to occur at high flow rates with relatively low relative branch flows (Hickman et al. 2012). These regions should be avoided when using thermal anemometers.

Example 2.

Step 1. Numerical Evaluation of Duct Average Velocity. Velocity measurements for a 610 × 610 mm square duct traverse using the log-T method are given in the following tables. Air density is ρ = 1.185 kg/m^3. Air temperature and absolute pressure conditions in the duct are 30.5°C and 103.3 kPa. The top row shows the horizontal traverse point position in the duct cross section, and the left column gives the vertical traverse point position (mm) in the duct cross-section. Note that, for this duct, there are 25 measurement positions across the duct, with 5 in each direction (see Figure 8 for how these positions are determined).

	Velocity Measurements, m/s				
	46 mm	**175 mm**	**305 mm**	**434 mm**	**564 mm**
46 mm	5.644	5.878	5.578	6.253	5.761
175 mm	6.142	6.330	5.949	6.452	6.325

Licensed for single user. © 2021 ASHRAE, Inc.

305 mm	6.182	6.980	6.655	6.965	6.360
434 mm	6.147	6.711	6.843	6.985	5.959
564 mm	5.796	5.781	5.690	5.832	5.928

Velocity Pressure Measurements, Pa

	46 mm	175 mm	305 mm	434 mm	564 mm
46 mm	18.87	20.47	18.43	23.17	19.66
175 mm	22.35	23.74	20.97	24.66	23.70
305 mm	22.65	28.87	26.24	28.74	23.97
434 mm	22.39	26.68	27.74	28.91	21.04
564 mm	19.91	19.80	19.18	20.15	20.82

The average air velocity is then

$$V_{ave} = \frac{1}{N}\sum_{i=1}^{N} V_i = \frac{(V_1 + V_2 + V_3 + V_4 + \cdots + V_N)}{N} = 6.203 \text{ m/s}$$

Alternatively, if local measurements are made in terms of velocity pressure p_w, the average velocity is

$$V_{ave} = \frac{1}{N}\sum_{i=1}^{N} V_i = C\sqrt{\frac{2}{\rho}}\left\{\frac{1}{N}\sum_{i=1}^{N}\sqrt{p_{w,i}}\right\}$$

$$= \sqrt{\frac{2}{1.185}}\left\{\frac{1}{25}\sum_{i=1}^{25}[\sqrt{18.87} + \sqrt{20.47} + \sqrt{18.43} + \cdots]\right\} = 6.203 \text{ m/s}$$

where the term in brackets represents the average of the square root of the individual velocity pressure measurements.

Step 2: Numerical Evaluation of Duct Volumetric Flow Rate. For the given duct cross-sectional area, the volumetric flow rate of air in cubic metres per second is then

$$Q_{Actual} = V_{ave}A = (6.203 \text{ m/s})(0.610 \times 0.610 \text{ m}) = 2.308 \text{ m}^3/\text{s}$$

where $A = 0.610 \times 0.610$ m is the duct cross-sectional area. The preceding actual volumetric flow rates can be converted to standard volumetric flow rates by referencing the flow rates to standard air density conditions for the same mass flow rate. The standard volumetric flow rate is the flow rate that would exist of the air were at standard air density conditions. Thus,

$$Q_{Standard} = Q_{Actual}\left(\frac{P_{Actual}}{P_{Standard}}\right)\left(\frac{T_{Standard}}{T_{Actual}}\right)$$

If standard conditions are defined as 21.1°C and 101.4 kPa, then the standard volumetric flow rate is

$$Q_{Standard} = (2.308 \text{ m/s})\left(\frac{103.3 \text{ kPa}}{101.4 \text{ kPa}}\right)\left(\frac{21.1 + 273.16}{30.5 + 273.16}\right) = 2.278 \text{ m/s}$$

Note: Different manufacturers can use different values for standard air density and standard conditions. It is very important to use a consistent set of standard conditions when comparing flow rates.

6.5 AIRFLOW-MEASURING HOODS

Flow-measuring hoods are portable instruments designed to measure supply or exhaust airflow through diffusers and grilles in HVAC systems. The assembly typically consists of a fabric hood section, a plastic or metal base, an airflow-measuring manifold, a meter, and handles for carrying and holding the hood in place.

For volumetric airflow measurements, the flow-measuring hood is placed over a diffuser or grille. The fabric hood captures and directs airflow from the outlet or inlet across the flow-sensing manifold in the base of the instrument. The manifold consists of a number of tubes containing upstream and downstream holes in a grid, designed to simultaneously sense and average multiple velocity points across the base of the hood. Air from the upstream holes flows through the tubes past a sensor and then exits through the downstream holes. Sensors used by different manufacturers include swinging vane anemometers, electronic micromanometers, and thermal anemometers. In electronic micromanometers, air does not actually flow through the manifold, but the airtight sensor senses the pressure differential from the upstream to downstream series of holes. The meter on the base of the hood interprets the signal from the sensor and provides a direct reading of volumetric flow in either an analog or digital display format.

As a performance check in the field, the indicated flow of a measuring hood can be compared to a duct traverse flow measurement (using a pitot-tube or thermal anemometer). All flow-measuring hoods induce some back pressure on the air-handling system because the hood restricts flow out of the diffuser. This added resistance alters the true amount of air coming out of the diffuser. In most cases, this error is negligible and is less than the accuracy of the instrument. For proportional balancing, this error need not be taken into account because all similar diffusers have about the same amount of back pressure. To determine whether back pressure is significant, a velocity traverse can be made in the duct ahead of the diffuser with and without the hood in place. The difference in average velocity of the traverse indicates the degree of back-pressure compensation required on similar diffusers in the system. For example, if the average velocity is 4.0 m/s with the hood in place and 4.1 m/s without the hood, the indicated flow reading can be multiplied by 1.025 on similar diffusers in the system (4.1/4.0 = 1.025). As an alternative, the designer of the air-handling system can predict the head-induced airflow reduction by using a curve supplied by the hood manufacturer. This curve indicates the pressure drop through the hood for different flow rates.

7. FLOW RATE MEASUREMENT

Various means of measuring fluid flow rate are listed in Table 5. Values for volumetric or mass flow rate measurement (ASME *Standard* PTC 19.5; Benedict 1984) are often determined by measuring pressure difference across an orifice, nozzle, or venturi tube. The various meters have different advantages and disadvantages. For example, the orifice plate is more easily changed than the complete nozzle or venturi tube assembly. However, the nozzle is often preferred to the orifice because its discharge coefficient is more precise. The venturi tube is a nozzle followed by an expanding recovery section to reduce net pressure loss. Differential pressure flow measurement has benefited through workshops addressing fundamental issues, textbooks, research, and improved standards (ASME *Standards* B40.100, MFC-1M, MFC-9M, MFC-10M; DeCarlo 1984; ISO *Standards* 5167:2003, 5801:2007; Mattingly 1984; Miller 1983).

Fluid meters use a wide variety of physical techniques to measure flow (ASME *Standard* PTC 19.5; DeCarlo 1984; Miller 1983); more common ones are described in this section. To validate accuracy of flow rate measurement instruments, calibration procedures should include documentation of traceability to the calibration facility. The calibration facility should, in turn, provide documentation of traceability to national standards.

Flow Measurement Methods

Direct. Both gas and liquid flow can be measured accurately by timing a collected amount of fluid that is measured gravimetrically or volumetrically. This method is common for calibrating other metering devices, but it is particularly useful where flow rate is low or intermittent and where a high degree of accuracy is required. These systems are generally large and slow, but in their simplicity, they can be considered primary devices.

Table 5 Volumetric or Mass Flow Rate Measurement

Measurement Means	Application	Nominal Range	Precision	Limitations
Orifice and differential pressure measurement system	Flow through pipes, ducts, and plenums for all fluids	Above Reynolds number of 5000	1 to 5%	Discharge coefficient and accuracy influenced by installation conditions.
Nozzle and differential pressure measurement system	Flow through pipes, ducts, and plenums for all fluids	Above Reynolds number of 5000	0.5 to 2.0%	Discharge coefficient and accuracy influenced by installation conditions.
Venturi tube and differential pressure measurement system	Flow through pipes, ducts, and plenums for all fluids	Above Reynolds number of 5000	0.5 to 2.0%	Discharge coefficient and accuracy influenced by installation conditions.
Timing given mass or volumetric flow	Liquids or gases; used to calibrate other flowmeters	Any	0.1 to 0.5%	System is bulky and slow.
Rotameters	Liquids or gases	Any	0.5 to 5.0%	Should be calibrated for fluid being metered.
Coriolis	Mass or volume; variable-density liquids or gases	As high as 907 kg/s	0.05 to 1.5%	
Displacement meter	Relatively small volumetric flow with high pressure loss	As high as 500 L/s, depending on type	0.1 to 2.0% depending on type	Most types require calibration with fluid being metered.
Gasometer or volume displacement	Short-duration tests; used to calibrate other flowmeters	Total flow limited by available volume of containers	0.5 to 1.0%	—
Thomas meter (temperature rise of stream caused by electrical heating)	Elaborate setup justified by need for good accuracy	Any	1%	Uniform velocity; usually used with gases.
Element of resistance to flow and differential pressure measurement system	Used for check where system has calibrated resistance element	Lower limit set by readable pressure drop	1 to 5%	Secondary reading depends on accuracy of calibration.
Turbine flowmeters	Liquids or gases	Any	0.25 to 2.0%	Uses electronic readout.
Single- or multipoint instrument for measuring velocity at specific point in flow	Primarily for installed air-handling systems with no special provision for flow measurement	Lower limit set by accuracy of velocity measurement instrumentation	2 to 10%	Accuracy depends on uniformity of flow and completeness of traverse. May be affected by disturbances near point of measurement.
Heat input and temperature changes with steam and water coil	Check value in heater or cooler tests	Any	1 to 3%	—
Laminar flow element and differential pressure measurement system	Measure liquid or gas volumetric flow rate; nearly linear relationship with pressure drop; simple and easy to use	50 mm^3/s to 1 m^3/s	1%	Fluid must be free of dirt, oil, and other impurities that could plug meter or affect its calibration.
Magnetohydrodynamic flowmeter (electromagnetic)	Measures electrically conductive fluids, slurries; meter does not obstruct flow; no moving parts	0.006 to 600 L/s	1%	At present state of the art, conductivity of fluid must be greater than 5 μmho/cm.
Swirl flowmeter and vortex shedding meter	Measure liquid or gas flow in pipe; no moving parts	Above Reynolds number of 10^4	1%	—

Licensed for single user. © 2021 ASHRAE, Inc.

The **variable-area meter** or **rotameter** is a convenient direct-reading flowmeter for liquids and gases. This is a vertical, tapered tube in which the flow rate is indicated by the position of a float suspended in the upward flow. The float's position is determined by its buoyancy and the upward fluid drag.

Displacement meters measure total liquid or gas flow over time. The two major types of displacement meters used for gases are the conventional gas meter, which uses a set of bellows, and the wet test meter, which uses a water displacement principle.

Indirect. The **Thomas meter** is used in laboratories to measure high gas flow rates with low pressure losses. Gas is heated by electric heaters, and the temperature rise is measured by two resistance thermometer grids. When heat input and temperature rise are known, the mass flow of gas is calculated as the quantity of gas that removes the equivalent heat at the same temperature rise.

A velocity traverse (made using a pitot tube or other velocity-measuring instrument) measures airflow rates in the field or calibrates large nozzles. This method can be imprecise at low velocities and impracticable where many test runs are in progress.

Another field-estimating method measures pressure drop across elements with known pressure drop characteristics, such as heating and cooling coils or fans. If the pressure drop/flow rate relationship has been calibrated against a known reference (typically, at least four points in the operating range), the results can be precise. If the method depends on rating data, it should be used for check purposes only.

7.1 VENTURI, NOZZLE, AND ORIFICE FLOWMETERS

Flow in a pipeline can be measured by a venturi meter (Figure 9), flow nozzle (Figure 10), or orifice plate (Figure 11). American Society of Mechanical Engineers (ASME) *Standard* MFC-3M describes measurement of fluid flow in pipes using the orifice, nozzle, and venturi; ASME *Standard* PTC 19.5 specifies their construction.

Assuming an incompressible fluid (liquid or slow-moving gas), uniform velocity profile, frictionless flow, and no gravitational effects, the principle of conservation of mass and energy can be applied to the venturi and nozzle geometries to give

$$w = \rho V_1 A_1 = \rho V_2 A_2 = A_2 \sqrt{\frac{2\rho(p_1 - p_2)}{1 - \beta^4}} \tag{7}$$

where

w = mass flow rate, kg/s
V = velocity of stream, m/s
A = flow area, m^2
ρ = density of fluid, kg/m^3
p = absolute pressure, Pa
β = ratio of diameters D_2/D_1 for venturi and sharp-edge orifice and d/D for flow nozzle, where D = pipe diameter and d = throat diameter

Note: Subscript 1 refers to entering conditions; subscript 2 refers to throat conditions.

Because flow through the meter is not frictionless, a correction factor C is defined to account for friction losses. If the fluid is at a high temperature, an additional correction factor F_a should be included to account for thermal expansion of the primary element. Because this amounts to less than 1% at 260°C, it can usually be omitted. Equation (7) then becomes

$$w = CA_2\sqrt{\frac{2\rho(p_1 - p_2)}{1-\beta^4}} \tag{8}$$

where C is the friction loss correction factor.

The factor C is a function of geometry and Reynolds number. Values of C are given in ASME *Standard* PTC 19.5. The jet passing through an orifice plate contracts to a minimum area at the vena contracta located a short distance downstream from the orifice plate. The contraction coefficient, friction loss coefficient C, and approach factor $1/(1-\beta^4)^{0.5}$ can be combined into a single constant K, which is a function of geometry and Reynolds number. The orifice flow rate equations then become

$$Q = KA_2\sqrt{\frac{2(p_1 - p_2)}{\rho}} \tag{9}$$

where

Q = discharge flow rate, m^3/s
A_2 = orifice area, m^2
$p_1 - p_2$ = pressure drop as obtained by pressure taps, Pa

Values of K are shown in ASME *Standard* PTC 19.5.

Valves, bends, and fittings upstream from the flowmeter can cause errors. Long, straight pipes should be installed upstream and downstream from flow devices to ensure fully developed flow for proper measurement. ASHRAE *Standard* 41.8 specifies upstream and downstream pipe lengths for measuring flow of liquids with an orifice plate. ASME *Standard* PTC 19.5 gives piping requirements between various fittings and valves and the venturi, nozzle, and orifice. If these conditions cannot be met, flow conditioners or straightening vanes can be used (ASME *Standards* PTC 19.5, MFC-10M; Mattingly 1984; Miller 1983).

Compressibility effects must be considered for gas flow if pressure drop across the measuring device is more than a few percent of the initial pressure.

Nozzles are sometimes arranged in parallel pipes from a common manifold; thus, the capacity of the testing equipment can be changed by shutting off the flow through one or more nozzles. An apparatus designed for testing airflow and capacity of air-conditioning equipment is described by Wile (1947), who also presents pertinent information on nozzle discharge coefficients, Reynolds numbers, and resistance of perforated plates. Some laboratories refer to this apparatus as a code tester.

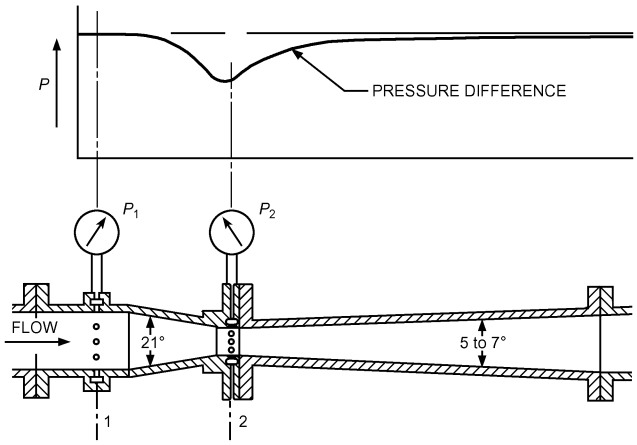

Fig. 9 Typical Herschel-Type Venturi Meter

7.2 VARIABLE-AREA FLOWMETERS (ROTAMETERS)

In permanent installations where high precision, ruggedness, and operational ease are important, the variable-area flowmeter is satisfactory. It is frequently used to measure liquids or gases in small-diameter pipes. For ducts or pipes over 150 mm in diameter, the expense of this meter may not be warranted. In larger systems,

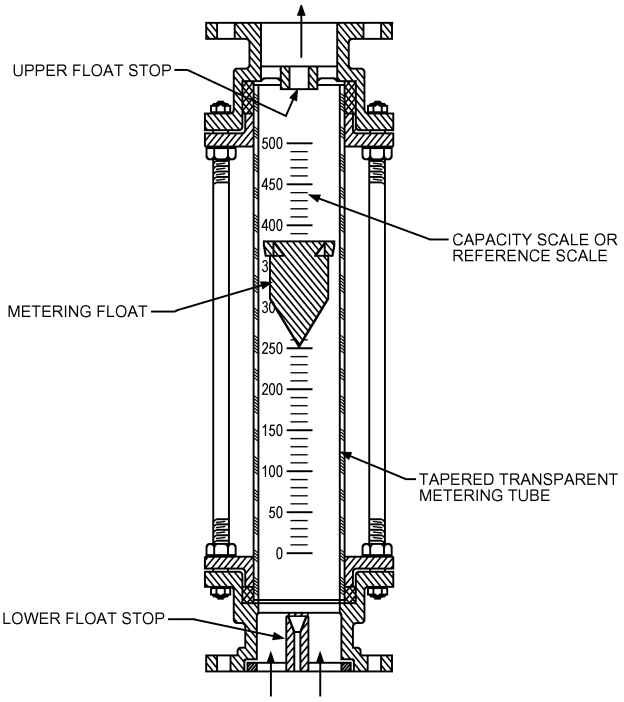

Fig. 12 Variable-Area Flowmeter

however, the meter can be placed in a bypass line and used with an orifice.

The variable-area meter (Figure 12) commonly consists of a float that is free to move vertically in a transparent tapered tube. The fluid to be metered enters at the narrow bottom end of the tube and moves upward, passing at some point through the annulus formed between the float and the inside wall of the tube. At any particular flow rate, the float assumes a definite position in the tube; a calibrated scale on the tube shows the float's location and the fluid flow rate.

The float's position is established by a balance between the fluid pressure forces across the annulus and gravity on the float. The buoyant force $V_f(\rho_f - \rho)g$ supporting the float is balanced by the pressure difference acting on the cross-sectional area of the float $A_f \Delta p$, where ρ_f, A_f, and V_f are, respectively, the float density, float cross-sectional area, and float volume. The pressure difference across the annulus is

$$\Delta p = \frac{V_f(\rho_f - \rho)g}{A_f} \tag{10}$$

The mass flow follows from Equation (9) as

$$w = KA_2\sqrt{\frac{2V_f(\rho_f - \rho)g\rho}{A_f}} \tag{11}$$

Flow for any fluid is nearly proportional to the area, so that calibration of the tube is convenient. To use the meter for different fluids, the flow coefficient variation for any float must be known. Float design can reduce variation of the flow coefficient with Reynolds number; float materials can reduce the dependence of mass flow calibration on fluid density.

7.3 CORIOLIS PRINCIPLE FLOWMETERS

Coriolis liquid flowmeters directly measure liquid mass flow rates. In a Coriolis flowmeter, the liquid flows through a vibrating sensor tube within the meter. An electromagnetic coil located on the sensor tube vibrates the tube in cantilever motion at a known frequency. The liquid enters the vibrating tube and is given the vertical momentum of the tube. The liquid in the entry portion of the sensor tube resists in the downward direction when the tube is moving upward. Conversely, when the tube is moving downward, the liquid in the exit portion of the sensor tube resists in the upward direction. Combined, these effects create a symmetrical twist angle. According to Newton's second law of motion, the amount of sensor tube twist angle is directly proportional to the mass flow rate of liquid flowing through the tube. Electromagnetic velocity sensors on opposing sides of the sensor tube measure the velocity of the vibrating tube. Mass flow rate is determined by measuring the time difference in the velocity measurements: the greater the time difference, the greater the mass flow rate. The measuring tubes are vibrated at their natural frequency; a change of the fluid mass inside the tubes causes a corresponding change to the tube's natural frequency. The frequency change of the tube is used to calculate the fluid density.

7.4 POSITIVE-DISPLACEMENT METERS

Many positive-displacement meters are available for measuring total liquid or gas volumetric flow rates. The measured fluid flows progressively into compartments of definite size. As the compartments fill, they rotate so that the fluid discharges from the meter. The flow rate through the meter equals the product of the compartment volume, number of compartments, and rotation rate of the rotor. Most of these meters have a mechanical register calibrated to show total flow.

7.5 TURBINE FLOWMETERS

Turbine flowmeters are volumetric flow-rate-sensing meters with a magnetic stainless steel turbine rotor suspended in the flow stream of a nonmagnetic meter body. The fluid stream exerts a force on the blades of the turbine rotor, setting it in motion and converting the fluid's linear velocity to an angular velocity. Design motivation for turbine meters is to have the rotational speed of the turbine

Licensed for single user. © 2021 ASHRAE, Inc.

proportional to the average fluid velocity and thus to the volume rate of fluid flow (DeCarlo 1984; Mattingly 1992; Miller 1983).

The rotor's rotational speed is monitored by an externally mounted pickoff assembly. The **magnetic pickoff** contains a permanent magnet and coil. As the turbine rotor blades pass through the field produced by the permanent magnet, a shunting action induces AC voltage in the winding of the coil wrapped around the magnet. A sine wave with a frequency proportional to the flow rate develops. With the **radio frequency pickoff**, an oscillator applies a high-frequency carrier signal to a coil in the pickoff assembly. The rotor blades pass through the field generated by the coil and modulate the carrier signal by shunting action on the field shape. The carrier signal is modulated at a rate corresponding to the rotor speed, which is proportional to the flow rate. With both pickoffs, pulse frequency is a measure of flow rate, and the total number of pulses measures total volume (Mattingly 1992; Shafer 1961; Woodring 1969).

Because output frequency of the turbine flowmeter is proportional to flow rate, every pulse from the turbine meter is equivalent to a known volume of fluid that has passed through the meter; the sum of these pulses yields total volumetric flow. Summation is done by electronic counters designed for use with turbine flowmeters; they combine a mechanical or electronic register with the basic electronic counter.

Turbine flowmeters should be installed with straight lengths of pipe upstream and downstream from the meter. The length of the inlet and outlet pipes should be according to manufacturers' recommendations or pertinent standards. Where recommendations of standards cannot be accommodated, the meter installation should be calibrated. Some turbine flowmeters can be used in bidirectional flow applications. A fluid strainer, used with liquids of poor or marginal lubricity, minimizes bearing wear.

The lubricity of the process fluid and the type and quality of rotor bearings determine whether the meter is satisfactory for the particular application. When choosing turbine flowmeters for use with fluorocarbon refrigerants, pay attention to the type of bearings used in the meter and to the refrigerant's oil content. For these applications, sleeve-type rather than standard ball bearings are recommended. The amount of oil in the refrigerant can severely affect calibration and bearing life.

In metering liquid fluorocarbon refrigerants, the liquid must not flash to a vapor (cavitate), which tremendously increases flow volume. Flashing results in erroneous measurements and rotor speeds that can damage bearings or cause a failure. Flashing can be avoided by maintaining adequate back pressure on the downstream side of the meter (Liptak 1972).

7.6 ELECTROMAGNETIC (MAG) FLOWMETERS

Magnetic flowmeters operate on the principle of Faraday's law of induction that states that the electromotive force induced in a circuit equals the negative of the time rate of change of the magnetic flux through the circuit. In a magnetic flowmeter, a magnetic field is electrically generated and channeled into the liquid flowing through the pipe. Faraday's law states that the voltage generated is proportional to the movement of the flowing liquid. Electronics in a magnetic flowmeter sense voltage and determine the volumetric flow rate. Magnetic tube flowmeters have no flow obstructions, so the pressure loss in these flowmeters is less than for many other types of flowmeters. Magnetic flowmeters require a minimum electrical conductivity. Most HVAC&R liquids have enough electrical conductivity to be used with these flowmeters.

7.7 VORTEX-SHEDDING FLOWMETERS

Vortex-shedding flowmeters are used to determine liquid velocities. Piezoelectric methods, strain-gage methods, or hot-film methods are used to sense dynamic pressure variations created by vortex shedding. The operating principle for these flowmeters is based on vortex shedding that occurs downstream of an immersed blunt-shaped solid body. As the liquid stream passes a blunt-shaped body, the liquid separates and generates small vortices that are shed alternately along and downstream of each side of the blunt-shaped body. Each vortex-shedding meter is designed to have a constant Strouhal number so that the vortex shedding frequency is proportional to the liquid flow velocity over a specified flow velocity range. The Strouhal number for each vortex shedding meter is experimentally determined by the flowmeter manufacturer and is provided with each vortex-shedding meter.

8. AIR INFILTRATION, AIRTIGHTNESS, AND OUTDOOR AIR VENTILATION RATE MEASUREMENT

Air infiltration is the flow of outdoor air into a building through unintentional openings. **Airtightness** refers to the building envelope's ability to withstand flow when subjected to a pressure differential. The **outdoor air ventilation rate** is the rate of outdoor airflow intentionally introduced to the building for dilution of occupant- and building-generated contaminants. Measurement approaches to determine these factors are described briefly here, and in greater detail in Chapter 16.

Air infiltration depends on the building envelope's airtightness and the pressure differentials across the envelope. These differentials are induced by wind, stack effect, and operation of building mechanical equipment. For meaningful results, the air infiltration rate should be measured under typical conditions.

Airtightness of a residential building's envelope can be measured relatively quickly using building pressurization tests. In this technique, a large fan or blower mounted in a door or window induces a large and roughly uniform pressure difference across the building shell. The airflow required to maintain this pressure difference is then measured. The more leakage in the building, the more airflow is required to induce a specific indoor/outdoor pressure difference. Building airtightness is characterized by the airflow rate at a reference pressure, normalized by the building volume or surface area. Under proper test conditions, results of a pressurization test are independent of weather conditions. Instrumentation requirements for pressurization testing include air-moving equipment, a device to measure airflow, and a differential pressure gage.

Commercial building envelope leakage can also be measured using building pressurization tests. Bahnfleth et al. (1999) describe a protocol for testing envelope leakage of tall buildings using the building's air-handling equipment.

Outdoor airflow can be measured directly using the flow rate measurement techniques described in this chapter. The flow measurement equipment must be appropriate for the required accuracy, operating conditions, range of airflows, and temperatures expected. The outdoor airflow rate is normally measured during testing and balancing, during commissioning, or for continuous ventilation flow rate control using permanently mounted flow sensors.

An additional factor that may be of interest is the building's air exchange rate, which compares airflow into the building with the building's volume. Typically, this includes both mechanical ventilation and infiltration. Building air exchange rates can be measured by injecting a tracer gas (ideally, a chemically stable, nontoxic gas not normally present in buildings) into a building and monitoring and analyzing the tracer gas concentration response. Equipment required for tracer testing includes (1) a means of injecting the tracer gas and (2) a tracer gas concentration measurement device, such as a gas chromatograph. Various tracer gas techniques are used, distinguished by their injection strategy and analysis approach. These techniques include constant concentration (equilibrium tracer),

Licensed for single user. © 2021 ASHRAE, Inc.

decay or growth (ASTM *Standard* E741), and constant injection. Decay is the simplest of these techniques, but the other methods may be satisfactory if care is taken. A common problem in tracer gas testing is poor mixing of the tracer gas with the airstreams being measured.

Carbon Dioxide

Carbon dioxide is often used as a tracer gas because CO_2 gas monitors are relatively inexpensive and easy to use, and occupant-generated CO_2 can be used for most tracer gas techniques. Bottled CO_2 or CO_2 fire extinguishers are also readily available for tracer gas injection. Carbon dioxide may be used as a tracer gas to measure ventilation rates under the conditions and methods described in ASTM *Standard* D6245, for diagnostic purposes and point-in-time snapshots of the system's ventilation capabilities. CO_2 sensors are also used in building controls strategies to avoid overventilation by approximating the level of occupancy in a space; this is one method of demand-controlled ventilation. The concentration output may be used in a mathematical formula that allows the system to modulate ventilation rates when spaces with high density have highly variable or intermittent occupancy (e.g., churches, theaters, gymnasiums). This method of control is less effective in lower-density occupancies and spaces with more stable populations (Persily and Emmerich 2001). Carbon dioxide may also be used together with outdoor air intake rate data to estimate the current population of a space.

CO_2 input for ventilation control does not address contaminants generated by the building itself, and therefore cannot be used without providing a base level of ventilation for non-occupant-generated contaminants that have been shown to total a significant fraction if not a majority of those found in the space.

9. CARBON DIOXIDE MEASUREMENT

Carbon dioxide has become an important measurement parameter for HVAC&R engineers, particularly in indoor air quality (IAQ) applications. Although CO_2 is generally not of concern as a specific toxin in indoor air, it is used as a surrogate indicator of odor related to human occupancy. ANSI/ASHRAE *Standard* 62.1 recommends specific minimum outdoor air ventilation rates to ensure adequate indoor air quality.

9.1 NONDISPERSIVE INFRARED CO_2 DETECTORS

The most widespread technology for IAQ applications is the nondispersive infrared (NDIR) sensor (Figure 13). This device uses the strong absorption band that CO_2 produces at 4.2 μm when excited by an infrared light source. IAQ-specific NDIR instruments, calibrated between 0 and 5000 ppm, are typically accurate within 150 ppm, but the accuracy of some sensors can be improved to within 50 ppm if the instrument is calibrated for a narrower range. Portable NDIR meters are available with direct-reading digital displays; however, response time varies significantly among different instruments. Most NDIR cell designs facilitate very rapid CO_2 sample diffusion, although some instruments now in widespread use respond more slowly, resulting in stabilization times greater than 5 min (up to 15 min), which may complicate walk-through inspections. CO_2 instruments can be classified as either single or dual wavelength. Single-wavelength instruments contain a single spectral filter at the absorption band of CO_2. This configuration is prone to drift as the infrared source ages and loses intensity. These instruments often use a self-adjustment procedure to compensate and require periodic exposure to outdoor CO_2 levels of approximately 400 ppm during periods when a building is unoccupied. This makes it impractical for buildings such as hospitals that are always occupied. Dual-wavelength instruments contain two spectral filters: one at the absorption band of CO_2 and one at a wavelength unaffected by any gases. This second filter allows the instrument to monitor the intensity of the infrared source to directly compensate for source aging.

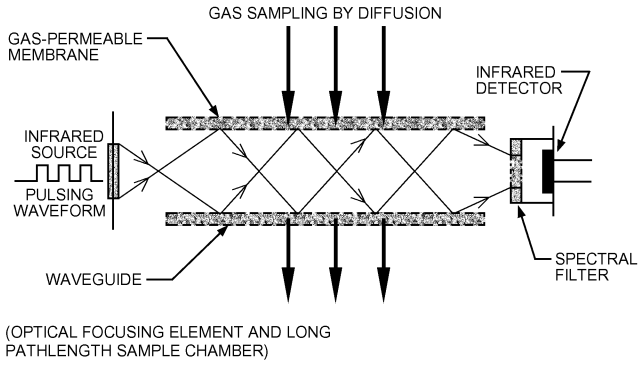

Fig. 13 Nondispersive Infrared Carbon Dioxide Sensor

Calibration

In a clean, stable environment, NDIR sensors can hold calibration for months, but condensation, dust, dirt, and mechanical shock may offset calibration. As with all other CO_2 sensor technologies, NDIR sensor readings are proportional to pressure, because the density of gas molecules changes when the sample pressure changes. This leads to errors in CO_2 readings when the barometric pressure changes from the calibration pressure. Weather-induced errors are small but should be considered when using CO_2 instruments at an altitude that is significantly different form the calibration altitude. Some instruments can accept a user adjustment to compensate for altitude. Instruments that do not have this ability should be recalibrated.

Some NDIR sensors are sensitive to cooling effects when placed in an airstream. This is an important consideration when locating a fixed sensor or when using a portable system to evaluate air-handling system performance, because airflow in supply and return ducts may significantly shift readings.

Applications

Nondispersive infrared sensors are well suited for equilibrium tracer and tracer decay ventilation studies, and faster-response models are ideal for a quick, basic evaluation of human-generated pollution and ventilation adequacy. When properly located, these sensors are also appropriate for continuous monitoring and for control strategies using equilibrium tracer and air fraction tracer calculations.

9.2 AMPEROMETRIC ELECTROCHEMICAL CO_2 DETECTORS

Amperometric electrochemical CO_2 sensors (Figure 14) use a measured current driven between two electrodes by the reduction of CO_2 that diffuses across a porous membrane. Unlike NDIR sensors, which normally last the lifetime of the instrument, electrochemical CO_2 sensors may change in electrolyte chemistry over time (typically 12 to 18 months) and should be replaced periodically. These sensors typically hold their calibration for several weeks, but they may drift more if exposed to low humidity; this drift makes them less suitable for continuous monitoring applications. At low humidity (below 30% rh), the sensors must be kept moist to maintain specified accuracy.

Amperometric electrochemical sensors require less power than NDIR sensors, usually operating continuously for weeks where NDIR

Licensed for single user. © 2021 ASHRAE, Inc.

instruments typically operate for 6 h (older models) to 150 h (newer models). The longer battery life can be advantageous for spot checks and walk-throughs, and for measuring CO_2 distribution throughout a building and within a zone. Unlike most NDIR sensors, amperometric electrochemical sensors are not affected by high humidity, although readings may be affected if condensate is allowed to form on the sensor.

9.3 PHOTOACOUSTIC CO_2 DETECTORS

Open-Cell Sensors

Open-cell photoacoustic CO_2 sensors (Figure 15) operate as air diffuses through a permeable membrane into a chamber that is pulsed with filtered light at the characteristic CO_2 absorption frequency of 4.2 µm. The light energy absorbed by the CO_2 heats the sample chamber, causing a pressure pulse, which is sensed by a piezoresistor. Open-cell photoacoustic CO_2 sensors are presently unavailable in portable instruments, in part because any vibration during transportation would affect calibration and might affect the signal obtained for a given concentration of CO_2. Ambient acoustical noise may also influence readings. For continuous monitoring, vibration is a concern, as are temperature and airflow cooling effects. However, if a sensor is located properly and the optical filter is kept relatively clean, photoacoustic CO_2 sensors may be very stable. Commercially available open-cell photoacoustic transmitters do not allow recalibration to adjust for pressure differences, so an offset should be incorporated in any control system using these sensors at an altitude or duct pressure other than calibration conditions.

Closed-Cell Sensors

Closed-cell photoacoustic sensors (Figure 16) operate under the same principle as the open-cell version, except that samples are pumped into a sample chamber that is sealed and environmentally stabilized. Two acoustic sensors are sometimes used in the chamber to minimize vibration effects. Closed-cell units, available as portable or fixed monitors, come with particle filters that are easily replaced (typically at 3- to 6-month intervals) if dirt or dust accumulates on them. Closed-cell photoacoustic monitors allow recalibration to correct for drift, pressure effects, or other environmental factors that might influence accuracy.

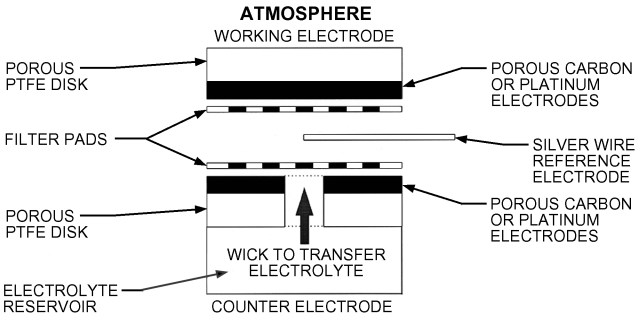

Fig. 14 Amperometric Carbon Dioxide Sensor

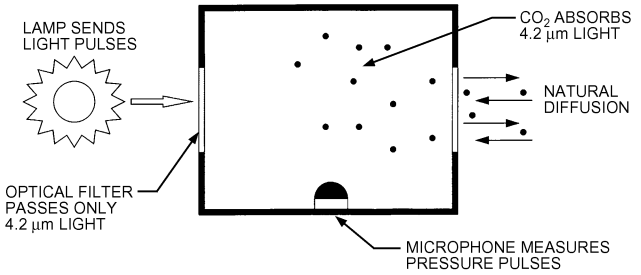

Fig. 15 Open-Cell Photoacoustic Carbon Dioxide Sensor

9.4 POTENTIOMETRIC ELECTROCHEMICAL CO_2 DETECTORS

Potentiometric electrochemical CO_2 sensors use a porous fluorocarbon membrane that is permeable to CO_2, which diffuses into a carbonic acid electrolyte, changing the electrolyte's pH. This change is monitored by a pH electrode inside the cell. The pH electrode isopotential drift prohibits long-term monitoring to the accuracy and resolution required for continuous measurement or control or for detailed IAQ evaluations, although accuracy within 100 ppm, achievable short-term over the 2000 ppm range, may be adequate for basic ventilation and odor evaluations. In addition, this type of sensor has a slow response, which increases the operator time necessary for field applications or for performing a walk-through of a building.

9.5 COLORIMETRIC DETECTOR TUBES

Colorimetric detector tubes contain a chemical compound that discolors in the presence of CO_2 gas, with the amount of discoloration related to the CO_2 concentration. These detector tubes are often used to spot-check CO_2 levels; when used properly, they are accurate to within 25%. If numerous samples are taken (i.e., six or more), uncertainty may be reduced. However, CO_2 detector tubes are generally not appropriate for specific ventilation assessment because of their inaccuracy and inability to record concentration changes over time.

9.6 LABORATORY MEASUREMENTS

Laboratory techniques for measuring CO_2 concentration include mass spectroscopy, thermal conductivity, infrared spectroscopy, and gas chromatography. These techniques typically require taking on-site **grab samples** for laboratory analysis. Capital costs for each piece of equipment are high, and significant training is required. A considerable drawback to grab sampling is that CO_2 levels change significantly during the day and over the course of a week, making it sensible to place sensors on site with an instrument capable of recording or data logging measurements continuously over the course of a workweek. An automated grab sampling system capturing many samples of data would be quite cumbersome and expensive if designed to provide CO_2 trend information over time. However, an advantage to laboratory techniques is that they can be highly accurate. A mass spectrometer, for example, can measure CO_2 concentration to within 5 ppm from 0 to 2000 ppm. All laboratory measurement techniques are subject to errors resulting from

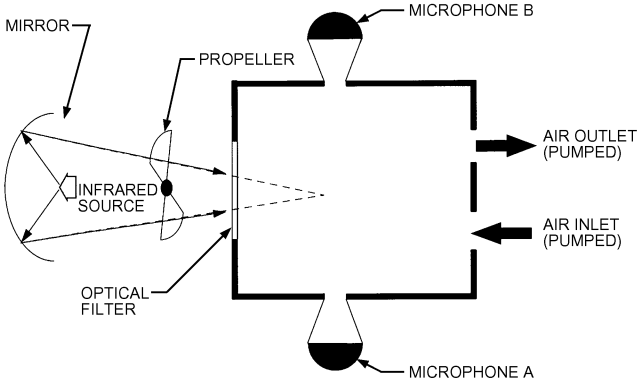

Fig. 16 Closed-Cell Photoacoustic Carbon Dioxide Sensor

Licensed for single user. © 2021 ASHRAE, Inc.

interfering agents. A gas chromatograph is typically used in conjunction with the mass spectrometer to eliminate interference from nitrous oxide (N_2O), which has an equivalent mass, if samples are collected in a hospital or in another location where N_2O might be present.

10. ELECTRIC MEASUREMENT

Ammeters

Ammeters are low-resistance instruments for measuring current. They should be connected in series with the circuit being measured (Figure 17). Ideally, they have the appearance of a short circuit, but in practice, all ammeters have a nonzero input impedance that influences the measurement to some extent.

Ammeters often have several ranges, and it is good practice when measuring unknown currents to start with the highest range and then reduce the range to the appropriate value to obtain the most sensitive reading. Ammeters with range switches maintain circuit continuity during switching. On some older instruments, it may be necessary to short-circuit the ammeter terminals when changing the range.

Current transformers are often used to increase the operating range of ammeters. They may also provide isolation/protection from a high-voltage line. Current transformers have at least two separate windings on a magnetic core (Figure 18). The primary winding is connected in series with the circuit in which the current is measured. In a clamp-on probe, the transformer core is actually opened and then connected around a single conductor carrying the current to be measured. That conductor serves as the primary winding. The secondary winding carries a scaled-down version of the primary current, which is connected to an ammeter. Depending on instrument type, the ammeter reading may need to be multiplied by the ratio of the transformer.

When using an auxiliary current transformer, the secondary circuit must not be open when current is flowing in the primary winding; dangerously high voltage may exist across the secondary terminals. A short-circuiting blade between the secondary terminals should be closed before the secondary circuit is opened at any point.

Transformer accuracy can be impaired by residual magnetism in the core when the primary circuit is opened at an instant when flux is large. The transformer core may be left magnetized, resulting in ratio and phase angle errors. The primary and secondary windings should be short-circuited before making changes.

Voltmeters

Voltmeters are high-resistance instruments that should be connected across the load (in parallel), as shown in Figure 19. Ideally, they have the appearance of an open circuit, but in practice, all voltmeters have some finite impedance that influences measurement to some extent.

Voltage transformers are often used to increase the operating range of a voltmeter (Figure 20). They also provide isolation from high voltages and prevent operator injury. Like current transformers, voltage transformers consist of two or more windings on a magnetic core. The primary winding is generally connected across the high voltage to be measured, and the secondary winding is connected to the voltmeter. It is important not to short-circuit the secondary winding of a voltage transformer.

Wattmeters

Wattmeters measure the active power of an AC circuit, which equals the voltage multiplied by that part of the current in phase with the voltage. There are generally two sets of terminals: one to connect the load voltage and the other to connect in series with the load current. Current and voltage transformers can be used to extend the range of a wattmeter or to isolate it from high voltage. Figures 21 and

Wattmeters with multiple current and voltage elements are available to measure polyphase power. Polyphase wattmeter connections are shown in Figures 24 and 25.

Power-Factor Meters

Power-factor meters measure the ratio of active to apparent power (product of voltage and current). Connections for power-factor meters and wattmeters are similar, and current and voltage transformers can be used to extend their range. Connections for single-phase and polyphase power-factor meters are shown in Figures 26 and 27, respectively.

11. ROTATIVE SPEED AND POSITION MEASUREMENT

Tachometers

Tachometers, or direct-measuring rpm counters, vary from hand-held mechanical or electric meters to shaft-driven and electronic pulse counters. They are used in general laboratory and shop work to check rotative speeds of motors, engines, and turbines.

Stroboscopes

Optical rpm counters produce a controlled high-speed electronic flashing light, which the operator directs on a rotating member, increasing the rate of flashes until reaching synchronism (the optical effect that rotation has stopped). At this point, the rpm measured is equal to the flashes per minute emitted by the strobe unit. Care must be taken to start at the bottom of the instrument scale and work up because multiples of the rpm produce almost the same optical effect as true synchronism. Multiples can be indicated by positioning suitable marks on the shaft, such as a bar on one side and a circle on the opposite side. If, for example, the two are seen superimposed, then the strobe light is flashing at an even multiple of the true rpm.

AC Tachometer-Generators

A tachometer-generator consists of a rotor and a stator. The rotor is a permanent magnet driven by the equipment. The stator is a winding with a hole through the center for the rotor. Concentricity is not critical; bearings are not required between rotor and stator. The output can be a single-cycle-per-revolution signal whose voltage is a linear function of rotor speed. The polypole configuration that generates 10 cycles per revolution allows measurement of speeds as low as 20 rpm without causing the indicating needle to flutter. The output of the AC tachometer-generator is rectified and connected to a DC voltmeter.

Optical (Shaft) Encoders

Optical encoders and linear glass scales can be used to measure rotational speed and both linear and angular position, depending on the geometry of the encoder. The output from an encoder is typically in the form of a pulse train. If this pulse train provides an indication of the absolute orientation (angle or position), it is called an **absolute encoder**. If it produces a relative pulse train with no absolute angle or position reference, it is called an **incremental encoder**. Modern high-resolution rotational (shaft) encoders typically consist of a shaft-mounted rotating disk containing regularly spaced slits. A light source is located on one side of the disk slits and a detector on the other side of the slits. As the disk rotates at a given frequency, a pulse train is produced at the detector from the intermittent pulses of light that pass through the rotating slits. Linear displacement encoders (absolute or incremental) operate on a similar principle, except that the slits are formed in a linear axis. Although modern encoders are typically optical, a resistive potentiometer can also be used as a position or rotation encoder, the output resistance being a direct indication of position or orientation.

12. SOUND AND VIBRATION MEASUREMENT

Measurement systems for determining sound pressure level, intensity level, and mechanical vibration generally use transducers to convert mechanical signals into electrical signals, which are then processed electronically or digitally to characterize the measured mechanical signals. These measurement systems contain one or more of the following elements, which may or may not be contained in a single instrument:

- A transducer, or an assembly of transducers, to convert sound pressure or mechanical vibration (time-varying strain, displacement, velocity, acceleration, or force) into an electrical signal that is quantitatively related to the mechanical quantity being measured
- Preamplifiers and amplifiers to provide functions such as preconditioning and amplification of signals, electrical impedance matching, signal conditioning, and gain
- Signal-processing equipment to quantify those aspects of the signal that are being measured (peak value, rms value, time-weighted average level, power spectral density, or magnitude or phase of a complex linear spectrum or transfer function) and conduct integration, differentiation, and frequency weighting of the signal
- Display and storage devices such as meters, oscilloscopes, digital displays, or level recorder to display and record the signal or the aspects of it that are being quantified
- An interface that allows cable, wireless, or memory card output

The relevant range of sound signals (i.e., audible to humans) can vary over more than six orders of magnitude in amplitude and more than three orders of magnitude in frequency, depending on the application. The relevant range of vibration signals may be slightly larger than this. References on instrumentation, measurement procedures, and signal analysis are given in the Bibliography. Product and application notes, technical reviews, and books published by instrumentation manufacturers are sources of additional reference material. See Chapter 48 of the 2019 *ASHRAE Handbook—HVAC Applications* and Chapter 8 of this volume for further information on sound and vibration.

12.1 SOUND MEASUREMENT

Microphones

A microphone is a transducer that transforms an acoustical signal into an electrical signal. The two predominant transduction principles used in sound measurement (as opposed to broadcasting) are the electrostatic and the piezoelectric. **Electrostatic (capacitor) microphones** are available either as electret microphones, which do not require an external polarizing voltage, or as condenser microphones, which do require an external polarizing voltage, typically in the range of 28 to 200 V (DC). **Piezoelectric microphones** may be manufactured using either natural piezoelectric crystals or poled ferroelectric crystals. The types of response characteristics of measuring microphones are pressure, free field, and random incidence (diffuse field).

The sensitivity and the frequency range over which the microphone has uniform sensitivity (flat frequency response) vary with sensing element diameter (surface area) and microphone type. Other critical factors that may affect microphone/preamplifier performance or response are atmospheric pressure, temperature, relative humidity, external magnetic and electrostatic fields, mechanical vibration, and radiation. Microphone selection is based on long- and short-term stability; the match between performance characteristics (e.g., sensitivity, frequency response, amplitude linearity, self-noise) and the expected amplitude of sound pressure, frequency, range of analysis, and expected environmental conditions of measurement; and any other pertinent considerations, such as size and directional characteristics.

Sound Measurement Systems

Microphone preamplifiers, amplifiers, weighting networks, filters, analyzers, and displays are available either separately or integrated into a measuring instrument such as a sound level meter, personal noise exposure meter (often called a noise dose meter or dosimeter), measuring amplifier, or real-time constant-percentage bandwidth (e.g., octave band) or narrow-band [e.g., fast Fourier transform (FFT)] frequency analyzer. Instruments included in a sound measurement system depend on the purpose of the measurement, the frequency range, and the resolution of the signal analysis. For community and industrial noise measurements for regulatory purposes, the instrument, signal processing, and quantity to be measured are usually dictated by the pertinent regulation. The optimal instrument set generally varies for measurement of different characteristics such as sound power in HVAC ducts, sound power emitted by machinery, noise criteria (NC) numbers, sound absorption coefficients, sound transmission loss of building partitions, and reverberation times (T_{60}).

Frequency Analysis

Measurement criteria often dictate using filters to analyze the signal, to indicate the spectrum of the sound being measured. Filters of different bandwidths for different purposes include fractional octave band (one, one-third, one-twelfth, etc.), constant-percentage bandwidth, and constant (typically narrow) bandwidth. The filters may be analog or digital and, if digital, may or may not be capable of real-time data acquisition during measurement, depending on the bandwidth of frequency analysis. FFT signal analyzers are generally used in situations that require very narrow-resolution signal analysis at constant bandwidth when the amplitudes of the sound spectra vary significantly with respect to frequency. This may occur in regions of resonance or when it is necessary to identify narrowband or discrete sine-wave signal components of a spectrum in the presence of other such components or of broadband noise. However, when the frequency varies (e.g., because of nonconstant rpm of a motor), results from FFT analyzers can be difficult to interpret because the change in rpm provides what looks like a broadband signal.

Sound Chambers

Special rooms and procedures are required to characterize and calibrate sound sources and receivers. The rooms are generally classified into three types: anechoic, hemianechoic, and reverberant. In the ideal **anechoic** room, all boundary surfaces completely absorb sound energy at all frequencies of interest. The ideal **hemianechoic** room would be identical to the ideal anechoic room, except that one surface would totally reflect sound energy at all frequencies. The ideal **reverberant** room would have boundary surfaces that totally reflect sound energy at all frequencies of interest.

Anechoic chambers are used to perform measurements under conditions approximating those of a free sound field. They can be used in calibrating and characterizing individual microphones, microphone arrays, acoustic intensity probes, reference sound power sources, loudspeakers, sirens, and other individual or complex sources of sound.

Hemianechoic chambers have a hard reflecting floor to accommodate heavy machinery or to simulate large factory floor or outdoor conditions. They can be used in calibrating and characterizing reference sound power sources, obtaining sound power levels of noise sources, and characterizing sound output of emergency vehicle sirens when mounted on an emergency motor vehicle.

Reverberation chambers are used to perform measurements under conditions approximating those of a diffuse sound field. They

Licensed for single user. © 2021 ASHRAE, Inc.

can be used in calibrating and characterizing random-incidence microphones and reference sound power sources, obtaining sound power ratings of equipment and sound power levels of noise sources, measuring sound absorption coefficients of building materials and panels, and measuring transmission loss through building partitions and components such as doors and windows.

The choice of which room type to use often depends on the test method required for the subject units, testing costs, or room availability.

Calibration

A measurement system should be calibrated as a system from microphone or probe to indicating device before it is used to perform absolute measurements of sound. Acoustic calibrators and pistonphones of fixed or variable frequency and amplitude are available for this purpose. These calibrators should be used at a frequency low enough that the pressure, free-field, and random-incidence response characteristics of the measuring microphone(s) are, for practical purposes, equivalent, or at least related in a known quantitative manner for that specific measurement system. In general, the sound pressure produced by these calibrators may vary, depending on microphone type, whether the microphone has a protective grid, atmospheric pressure, temperature, and relative humidity. Correction factors and coefficients are required when conditions of use differ from those existing during the calibration of the acoustic calibrator or pistonphone. For demanding applications, precision sound sources and measuring microphones should periodically be sent to the manufacturer, a private testing laboratory, or a national standards laboratory for calibration.

12.2 VIBRATION MEASUREMENT

Except for seismic instruments that record or indicate vibration directly with a mechanical or optomechanical device connected to the test surface, vibration measurements use an electromechanical or interferometric vibration transducer. Here, the term **vibration transducer** refers to a generic electromechanical vibration transducer. Electromechanical and interferometric vibration transducers belong to a large and varied group of transducers that detect mechanical motion and furnish an electrical signal that is quantitatively related to a particular physical characteristic of the motion. Depending on design, the electrical signal may be related to mechanical strain, displacement, velocity, acceleration, or force. The operating principles of vibration transducers may involve optical interference; electrodynamic coupling; piezoelectric (including poled ferroelectric) or piezoresistive crystals; or variable capacitance, inductance, reluctance, or resistance. A considerable variety of vibration transducers with a wide range of sensitivities and bandwidths is commercially available. Vibration transducers may be contacting (e.g., seismic transducers) or noncontacting (e.g., interferometric, optical, or capacitive).

Transducers

Seismic transducers use a spring-mass resonator within the transducer. At frequencies much greater than the fundamental natural frequency of the mechanical resonator, the relative displacement between the base and the seismic mass of the transducer is nearly proportional to the displacement of the transducer base. At frequencies much lower than the fundamental resonant frequency, the relative displacement between the base and the seismic mass of the transducer is nearly proportional to the acceleration of the transducer base. Therefore, seismic displacement transducers and seismic electrodynamic velocity transducers tend to have a relatively compliant suspension with a low resonant frequency; piezoelectric accelerometers and force transducers have a relatively stiff suspension with a high resonant frequency.

Strain transducers include the metallic resistance gage and piezoresistive strain gage. For dynamic strain measurements, these are usually bonded directly to the test surface. The accuracy with which a bonded strain gage replicates strain occurring in the test structure is largely a function of how well the strain gage was oriented and bonded to the test surface.

Displacement transducers include the capacitance gage, fringe-counting interferometer, seismic displacement transducer, optical approaches, and the linear variable differential transformer (LVDT). Velocity transducers include the reluctance (magnetic) gage, laser Doppler interferometer, and seismic electrodynamic velocity transducer. Accelerometers and force transducers include the piezoelectric, piezoresistive, and force-balance servo.

Vibration Measurement Systems

Sensitivity, frequency limitations, bandwidth, and amplitude linearity of vibration transducers vary greatly with the transduction mechanism and the manner in which the transducer is applied in a given measurement apparatus. Contacting transducers' performance can be significantly affected by the mechanical mounting methods and points of attachment of the transducer and connecting cable and by the mechanical impedance of the structure loading the transducer. Amplitude linearity varies significantly over the operating range of the transducer, with some transducer types or configurations being inherently more linear than others. Other factors that may critically affect performance or response are temperature; relative humidity; external acoustic, magnetic, and electrostatic fields; transverse vibration; base strain; chemicals; and radiation. A vibration transducer should be selected based on its long- and short-term stability; the match between its performance characteristics (e.g., sensitivity, frequency response, amplitude linearity, self-noise) and the expected amplitude of vibration, frequency range of analysis, and expected environmental conditions of measurement; and any other pertinent considerations (e.g., size, mass, resonant frequency).

Vibration exciters, or **shakers**, are used in structural analysis, vibration analysis of machinery, fatigue testing, mechanical impedance measurements, and vibration calibration systems. Vibration exciters have a table or moving element with a drive mechanism that may be mechanical, electrodynamic, piezoelectric, or hydraulic. They range from relatively small, low-power units for calibrating transducers (e.g., accelerometers) to relatively large, high-power units for structural and fatigue testing.

Conditioning amplifiers, power supplies, preamplifiers, charge amplifiers, voltage amplifiers, power amplifiers, filters, controllers, and displays are available either separately or integrated into a measuring instrument or system, such as a structural analysis system, vibration analyzer, vibration monitoring system, vibration meter, measuring amplifier, multichannel data-acquisition and modal analysis system, or real-time fractional-octave or FFT signal analyzer. The choice of instruments to include in a vibration measurement system depends on the mechanical quantity to be determined, purpose of measurement, and frequency range and resolution of signal analysis. For vibration measurements, the signal analysis is relatively narrow in bandwidth and may be relatively low in frequency, to accurately characterize structural resonances. Accelerometers with internal integrated circuitry are available to provide impedance matching or servo control for measuring very-low-frequency acceleration (servo accelerometers). Analog integration and differentiation of vibration signals are available through integrating and differentiating networks and amplifiers, and digital is available through FFT analyzers. Vibration measurements made for different purposes (e.g., machinery diagnostics and health monitoring, balancing rotating machinery, analysis of torsional vibration, analysis of machine-tool vibration, modal analysis, analysis of vibration isolation, stress monitoring, industrial control) generally have

Licensed for single user. © 2021 ASHRAE, Inc.

different mechanical measurement requirements and a different optimal set of instrumentation.

Calibration

Because of their inherent long- and short-term stability, amplitude linearity, wide bandwidth, wide dynamic range, low noise, and wide range of sensitivities, seismic accelerometers have traditionally been used as a reference standard for dynamic mechanical measurements. A measurement system should be calibrated as a system from transducer to indicating device before it is used to perform absolute dynamic measurements of mechanical quantities. Calibrated reference vibration exciters, standard reference accelerometers, precision conditioning amplifiers, and precision calibration exciters are available for this purpose. These exciters and standard reference accelerometers can be used to transfer a calibration to another transducer. For demanding applications, a calibrated exciter or standard reference accelerometer with connecting cable and conditioning amplifier should periodically be sent to the manufacturer, a private testing laboratory, or a national standards laboratory for calibration.

13. LIGHTING MEASUREMENT

Light level, or **illuminance**, is usually measured with a photocell made from a semiconductor such as silicon or selenium. Photocells produce an output current proportional to incident luminous flux when linked with a microammeter, color- and cosine-corrected filters, and multirange switches; they are used in inexpensive handheld light meters and more precise instruments. Different cell heads allow multirange use in precision meters.

Cadmium sulfide photocells, in which resistance varies with illumination, are also used in light meters. Both gas-filled and vacuum photoelectric cells are in use.

Small survey-type meters are not as accurate as laboratory meters; their readings should be considered approximate, although consistent, for a given condition. Their range is usually from 50 to 50 000 lux. Precision low-level meters have cell heads with ranges down to 0 to 20 lux.

A photometer installed in a revolving head is called a **goniophotometer** and is used to measure the distribution of light sources or luminaires. To measure total luminous flux, the luminaire is placed in the center of a sphere painted inside with a high-reflectance white with a near-perfect diffusing matte surface. Total light output is measured through a small baffled window in the sphere wall.

To measure irradiation from germicidal lamps, a filter of fused quartz with fluorescent phosphor is placed over the light meter cell.

If meters are used to measure the number of lumens per unit area diffusely leaving a surface, luminance (cd/m^2) instead of illumination (lux) is read. Light meters can be used to measure luminance, or electronic lux meters containing a phototube, an amplifier, and a microammeter can read luminance directly.

Chapter 9 of the IES (2011) *Lighting Handbook* gives detailed information on measurement of light.

14. THERMAL COMFORT MEASUREMENT

Thermal comfort depends on the combined influence of clothing, activity, air temperature, air velocity, mean radiant temperature, and air humidity. Thermal comfort is influenced by heating or cooling of particular body parts through radiant temperature asymmetry (plane radiant temperature), draft (air temperature, air velocity, turbulence), vertical air temperature differences, and floor temperature (surface temperature).

A general description of thermal comfort is given in Chapter 9, and guidelines for an acceptable thermal environment are given in ASHRAE *Standard* 55 and ISO *Standard* 7730. ASHRAE *Standard* 55 also includes required measuring accuracy. In addition to specified accuracy, ISO *Standard* 7726 includes recommended measuring locations and a detailed description of instruments and methods.

Clothing and Activity Level

These values are estimated from tables (Chapter 9; ISO *Standards* 8996, 9920). Thermal insulation of clothing [(m^2·K)/W] can be measured on a thermal mannequin (McCullough et al. 1985; Olesen 1985). Activity (W/m^2) can be estimated from measuring CO_2 and O_2 in a person's expired air.

Air Temperature

Various types of thermometers may be used to measure air temperature. Placed in a room, the sensor registers a temperature between air temperature and mean radiant temperature. One way of reducing the radiant error is to make the sensor as small as possible, because the convective heat transfer coefficient increases as size decreases, whereas the radiant heat transfer coefficient is constant. A smaller sensor also provides a favorably low time constant. Radiant error can also be reduced by using a shield (an open, polished aluminum cylinder) around the sensor, using a sensor with a low-emittance surface, or artificially increasing air velocity around the sensor (aspirating air through a tube in which the sensor is placed).

Air Velocity

In occupied zones, air velocities are usually small (0 to 0.5 m/s), but do affect thermal sensation. Because velocity fluctuates, the mean value should be measured over a suitable period, typically 3 min. Velocity fluctuations with frequencies up to 1 Hz significantly increase human discomfort caused by draft, which is a function of air temperature, mean air velocity, and turbulence (see Chapter 9). Fluctuations can be given as the standard deviation of air velocity over the measuring period (3 min) or as the turbulence intensity (standard deviation divided by mean air velocity). Velocity direction may change and is difficult to identify at low air velocities. An omnidirectional sensor with a short response time should be used. A thermal anemometer is suitable. If a hot-wire anemometer is used, the direction of measured flow must be perpendicular to the hot wire. Smoke puffs can be used to identify the direction.

Plane Radiant Temperature

This refers to the uniform temperature of an enclosure in which the radiant flux on one side of a small plane element is the same as in the actual nonuniform environment. It describes the radiation in one direction. Plane radiant temperature can be calculated from surface temperatures of the environment (half-room) and angle factors between the surfaces and a plane element (ASHRAE *Standard* 55). It may also be measured by a net-radiometer or a radiometer with a sensor consisting of a reflective disk (polished) and an absorbent disk (painted black) (Olesen et al. 1989).

Mean Radiant Temperature

This is the uniform temperature of an imaginary black enclosure in which an occupant would exchange the same amount of radiant heat as in the actual nonuniform enclosure. Mean radiant temperature can be calculated from measured surface temperatures and the corresponding angle factors between the person and surfaces. It can also be determined from the plane radiant temperature in six opposite directions, weighted according to the projected area factors for a person. For more information, see Chapter 9.

Licensed for single user. © 2021 ASHRAE, Inc.

Because of its simplicity, the instrument most commonly used to determine the mean radiant temperature is a **black globe thermometer** (Bedford and Warmer 1935; Vernon 1932). This thermometer consists of a hollow sphere usually 150 mm in diameter, coated in flat black paint with a thermocouple or thermometer bulb at its center. The temperature assumed by the globe at equilibrium results from a balance between heat gained and lost by radiation and convection.

Mean radiant temperatures are calculated from

$$\bar{t}_r = \left[(t_g + 273)^4 + \frac{1.10 \times 10^8 V_a^{0.6}}{\varepsilon D^{0.4}} (t_g - t_a) \right]^{1/4} - 273 \qquad (12)$$

where

$\bar{t}_r$ = mean radiant temperature, °C
t_g = globe temperature, °C
V_a = air velocity, m/s
t_a = air temperature, °C
D = globe diameter, m
ε = emissivity (0.95 for black globe)

According to Equation (12), air temperature and velocity around the globe must also be determined. The globe thermometer is spherical, but mean radiant temperature is defined in relation to the human body. For sedentary people, the globe represents a good approximation. For people who are standing, the globe, in a radiant nonuniform environment, overestimates the radiation from floor or ceiling; an ellipsoidal sensor gives a closer approximation. A black globe also overestimates the influence of short-wave radiation (e.g., sunshine). A flat gray color better represents the radiant characteristic of normal clothing (Olesen et al. 1989). The hollow sphere is usually made of copper, which results in an undesirably high time constant. This can be overcome by using lighter materials (e.g., a thin plastic bubble).

Air Humidity

The water vapor pressure (absolute humidity) is usually uniform in the occupied zone of a space; therefore, it is sufficient to measure absolute humidity at one location. Many of the instruments listed in Table 3 are applicable. At ambient temperatures that provide comfort or slight discomfort, the thermal effect of humidity is only moderate, and highly accurate humidity measurements are unnecessary.

14.1 CALCULATING THERMAL COMFORT

When the thermal parameters have been measured, their combined effect can be calculated by the thermal indices in Chapter 9. For example, the effective temperature (Gagge et al. 1971) can be determined from air temperature and humidity. Based on the four environmental parameters and an estimation of clothing and activity, the **predicted mean vote** (PMV) can be determined with the aid of tables (Chapter 9; Fanger 1982; ISO *Standard* 7730). The PMV is an index predicting the average thermal sensation that a group of occupants may experience in a given space.

For certain types of normal activity and clothing, measured environmental parameters can be compared directly with those in ASHRAE *Standard* 55 or ISO *Standard* 7730.

14.2 INTEGRATING INSTRUMENTS

Several instruments have been developed to evaluate the combined effect of two or more thermal parameters on human comfort. Madsen (1976) developed an instrument that gives information on the occupants' expected thermal sensation by directly measuring the PMV value. The comfort meter has a heated elliptical sensor that simulates the body (Figure 28). The estimated clothing (insulation value), activity in the actual space, and humidity are set on the instrument. The sensor then integrates the thermal effect of air temperature, mean radiant temperature, and air velocity in approximately the same way the body does. The electronic instrument gives the measured operative and equivalent temperature, calculated PMV, and predicted percentage of dissatisfied (PPD).

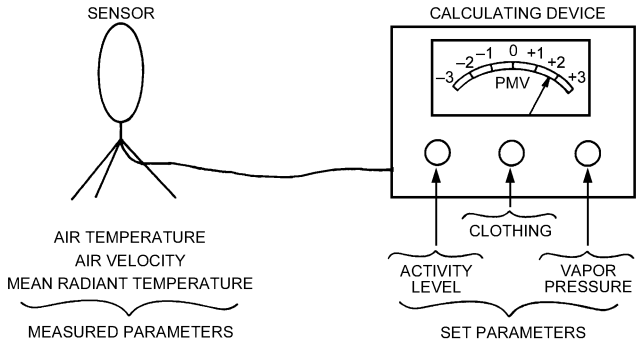

Fig. 28 Madsen's Comfort Meter
(Madsen 1976)

15. MOISTURE CONTENT AND TRANSFER MEASUREMENT

Moisture commonly refers to the presence of liquid and vapor states of water, which has two positively charged hydrogen atoms and one negatively charged oxygen atom. As moisture vapor and liquid molecules adsorb to a hygroscopic material (e.g., most porous building materials), the material's **moisture content (MC)** increases significantly. The presence of moisture in materials influences their performance (e.g., thermal insulation, acoustics, processability, dielectricity, storage life, unhealthy microbe growth, corrosion, chemical aspects).

However, little off-the-shelf instrumentation exists to measure the moisture content or transfer of porous materials, although many measurements can be set up with a small investment of time and money. Three moisture properties are most commonly sought: (1) moisture content; (2) vapor permeability (rate at which water vapor passes through a given material); and (3) liquid diffusivity (rate at which liquid water passes through a porous material).

Moisture Content

MC can be classified into four categories:

- **Wet-basis volumetric MC:** ratio of moisture's volume to wet sample's bulk volume
- **Wet-basis mass MC:** ratio of moisture's mass to wet sample's bulk mass
- **Dry-basis volumetric MC:** ratio of moisture's volume to dry sample's bulk volume
- **Dry-basis mass MC:** ratio of moisture's mass to dry sample's bulk mass

Dry basis is often used in building materials.

The MC of a material is usually described with a **sorption isotherm**, which relates the **equilibrium moisture content (EMC)** of a hygroscopic material to the ambient relative humidity under constant temperature. Determining a sorption isotherm involves exposing a sample of material to a known relative humidity at a known temperature and then measuring the sample's moisture content after enough time has elapsed for the sample to reach equilibrium with its surroundings. Hysteresis in the sorption behavior of most hygroscopic materials requires that measurements be made for both increasing (adsorption isotherm) and decreasing relative humidity (desorption isotherm). Figure 29 shows hysteresis through the

Licensed for single user. © 2021 ASHRAE, Inc.

adsorption and desorption isotherms for a typical hygroscopic porous material (Straube 1998). Three different regimes of moisture storage are shown: sorption or hygroscopic (A), capillary (B), and oversaturated (C). In the hygroscopic regime, water vapor adsorbs to the pore walls. As relative humidity increases, adsorbed moisture molecules grow from single layers to multiple interconnected layers (internal capillary condensation). The capillary regime (B) is somewhat arbitrarily designated as that part of the moisture storage function above the critical moisture content. Physically, it is presumed that a continuous liquid phase forms. Finally, in the supersaturated state, the relative humidity is always 100% and no more water will wick into a material.

Ambient relative humidity can be controlled using saturated salt solutions or mechanical refrigeration equipment (Carotenuto et al. 1991; Cunningham and Sprott 1984; Tveit 1966). Precise measurements of the relative humidity produced by various salt solutions were reported by Greenspan (1977). ASTM *Standard* E104 describes the use of saturated salt solutions. A sample's EMC is usually determined gravimetrically using a precision balance. The sample's dry mass, necessary to calculate moisture content, can be found by oven or desiccant drying. Oven dry mass may be lower than desiccant dry mass because of the loss of volatiles other than water in the oven (Richards et al. 1992).

A major difficulty in measuring sorption isotherms of engineering materials is the long time required for many materials to reach equilibrium (often as long as weeks or months). The rate-limiting mechanism for these measurements is usually the slow process of vapor diffusion into the pores of the material. Using smaller samples can reduce diffusion time. Note that, although EMC isotherms are traditionally plotted as a function of relative humidity, the actual transport to or from materials is determined by vapor pressure differences. Thus, significant moisture content changes can occur because of changes in either the material vapor pressure or the surrounding air long before equilibrium is reached.

Moisture content can be directly or indirectly determined. Direct techniques measure moisture by a chemical reaction (e.g., Karl Fisher titration) or using the difference in mass before and after drying a test sample. Using chemical reactions is complex, slow, and expensive, and uses toxic chemicals, so it is seldom used. Mass loss after drying is usually referred to as the **loss on drying (LOD)** or **thermo-gravimetric method** (or simply **gravimetric**), in which a sample is weighed, heated in an oven at a set temperature (e.g., 100 to 105°C) for an appropriate period to a constant weight, cooled in the dry atmosphere, and reweighed. Although these direct methods are accurate (within ±0.01 m^3/m^3), they are time-consuming, destructive, and do not allow for in situ measurement. Therefore, many indirect methods have been developed. Unlike direct measurements, indirect techniques do not involve removing moisture in a sample: they estimate moisture content by a strong or calibrated relationship with some other measurable variables such as dielectric permittivity or thermal conductivity. Both empirical and theoretical equations between the moisture content and measurable variable are used for the calibration.

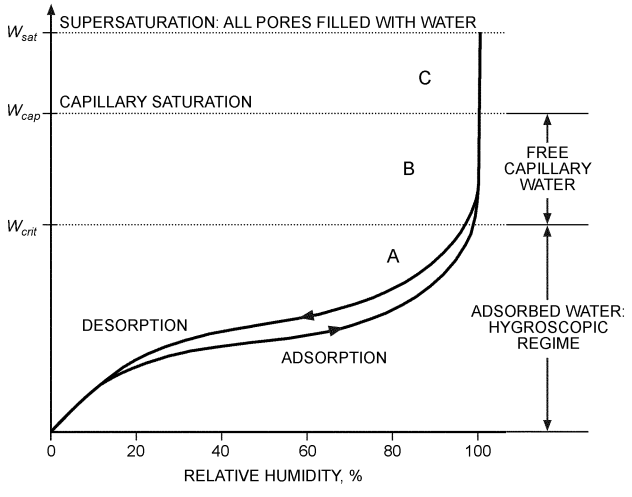

Fig. 29 Adsorption Isotherm and Desorption Isotherm for Hygroscopic Material
(Straube 1998)

Major types of indirect methods include neutron moderation, gamma ray attenuation, nuclear magnetic resonance, microwave reflectance and attenuation, near-infrared reflectance or transmission (NIR/T), dielectric techniques, and thermal methods. Safety issues may limit application of the first three techniques, although they have some advantages such as robustness or high accuracy. NIR/T is a rapid, noninvasive technique for determining moisture content in several applications (e.g., in grain). Its limiting factors include high cost, low penetration depth, and a large sample size required for calibration.

Dielectric techniques take advantage of the strong dependence of the composite material's bulk permittivity (or dielectric constant) on moisture content. Because the permittivity of water (K_{aw} = 81) is much higher than that of the porous material's other constituents (e.g., 1 for air, 4.7 for fiberglass), the total permittivity of the composite porous material is mainly determined by the moisture content. Dielectric methods include time domain reflectometry (TDR), frequency domain (FD), amplitude domain reflectometry (ADR), phase transmission (Virrib), and time domain transmission (TDT). These dielectric moisture content sensors are becoming popular in various field and laboratory applications (e.g., soil, wood) because they have short response time (almost instantaneous measurements), do not require maintenance, and can provide good accuracy (commercial devices can be accurate within ±0.02 or 0.03 m^3/m^3 and up to ±0.01 m^3/m^3 in some more specific situations). However, their sensitivity to boundary water or salinity limits their applications in a highly saline/conductive condition.

Thermal techniques are increasingly considered as an alternative to other methodologies to determine moisture content in porous materials. The main attractions in pursuing this technology are simultaneous measurements of other thermophysical properties (e.g., thermal conductivity, thermal diffusivity, volumetric heat capacity, and water matric potential), wide measurement range, invulnerability of salinity, low cost, high accuracy and robustness. Two predominant concerns limiting the development of the thermal technique include slow reaction time (one commercial product with the accuracy of ±0.01 m^3/m^3 has the response time of two minutes) and requirement of good contact with the test sample. One typical example of the thermal method identifies moisture content θ_y by its relationship with volumetric specific heat capacity ρc, as described by Bristow et al. (1993, 1994), Campbell et al. (1991), and Yang et al. (2015).

There is no universal method of moisture content measurement suitable to every application, and detected moisture content varies with measurement method. The suitability of each method relies on different application considerations such as safety, cost, accuracy, response time, installation, ease of operation, management, and durability.

Vapor Permeability

Diffusive transfer of water vapor through porous materials is often described by a modified form of Fick's law:

$$w''_v = -\mu \frac{dp}{dx} \tag{13}$$

Licensed for single user. © 2021 ASHRAE, Inc.

where

w_v'' = mass of vapor diffusing through unit area per unit time, mg/(s·m^2)
dp/dx = vapor pressure gradient, kPa/m
μ = vapor permeability, mg/(s·m·kPa)

In engineering practice, permeance may be used instead of permeability. **Permeance** is simply permeability divided by the material thickness in the direction of vapor flow; thus, permeability is a material property, whereas permeance depends on thickness.

Permeability is measured with wet-cup, dry-cup, or modified cup tests. Specific test methods for measuring water vapor permeability are given in ASTM *Standard* E96.

For many engineering materials, vapor permeability is a strong function of mean relative humidity. Wet and dry cups cannot adequately characterize this dependence on relative humidity. Instead, a modified cup method can be used, in which pure water or desiccant in a cup is replaced with a saturated salt solution (Burch et al. 1992; McLean et al. 1990). A second saturated salt solution is used to condition the environment outside the cup. Relative humidities on both sides of the sample material can be varied from 0 to 100%. Several cups with a range of mean relative humidities are used to map out the dependence of vapor permeability on relative humidity.

In measuring materials of high permeability, the finite rate of vapor diffusion through air in the cup may become a factor. Air-film resistance could then be a significant fraction of the sample's resistance to vapor flow. Accurate measurement of high-permeability materials may require an accounting of diffusive rates across all air gaps (Fanney et al. 1991).

Liquid Diffusivity

Transfer of liquid water through porous materials may be characterized as a diffusion-like process:

$$w_l'' = -\rho D_l \frac{d\gamma}{dx} \tag{14}$$

where

w_l'' = mass of liquid transferred through unit area per unit time, kg/(s·m^2)
ρ = liquid density, kg/m^3
D_l = liquid diffusivity, m^2/s
$d\gamma/dx$ = moisture content gradient, m^{-1}

D_l typically depends strongly on moisture content.

Transient measurement methods deduce the functional form of $D_l\gamma$ by observing the evolution of a one-dimensional moisture content profile over time. An initially dry specimen is brought into contact with liquid water. Free water migrates into the specimen, drawn in by surface tension. The resulting moisture content profile, which changes with time, must be differentiated to find the material's liquid diffusivity (Bruce and Klute 1956).

Determining the transient moisture content profile typically involves a noninvasive and nondestructive method of measuring local moisture content. Methods include gamma ray absorption (Freitas et al. 1991; Kumaran and Bomberg 1985; Quenard and Sallee 1989), x-ray radiography (Ambrose et al. 1990), neutron radiography (Prazak et al. 1990), and nuclear magnetic resonance (NMR) (Gummerson et al. 1979).

Uncertainty in liquid diffusivity measurement is often large because of the need to differentiate noisy experimental data.

16. HEAT TRANSFER THROUGH BUILDING MATERIALS

Thermal Conductivity

The thermal conductivity of a heat insulator, as defined in Chapter 25, is a unit heat transfer factor. Two methods of determining the thermal conductivity of flat insulation are the **guarded hot plate** and the **heat flow meter apparatus**, according to ASTM *Standards* C177 and C518, respectively. Both methods use parallel isothermal plates to induce a steady temperature gradient across the thickness of the specimen(s). The guarded hot plate is considered an absolute method for determining thermal conductivity. The heat flow meter apparatus requires calibration with a specimen of known thermal conductivity, usually determined in the guarded hot plate. The heat flow meter apparatus is calibrated by determining the voltage output of its heat flux transducer(s) as a function of the heat flux through the transducer(s).

Basic guarded hot plate design consists of an electrically heated plate and two liquid-cooled plates. Two similar specimens of a material are required for a test; one is mounted on each side of the hot plate. A cold plate is then pressed against the outside of each specimen by a clamp screw. The heated plate consists of two sections separated by a small gap. During tests, the central (metering) and outer (guard) sections are maintained at the same temperature to minimize errors caused by edge effects. The electric energy required to heat the metering section is measured carefully and converted to heat flow. Thermal conductivity of the material can be calculated under steady-state conditions using this heat flow quantity, area of the metering section, temperature gradient, and specimen thickness. Thermal conductivity of cylindrical or pipe insulation (Chapter 25) is determined similarly, but an equivalent thickness must be calculated to account for the cylindrical shape (ASTM *Standard* C335). Transient methods have been developed by D'Eustachio and Schreiner (1952), Hooper and Chang (1953), and Hooper and Lepper (1950) using a line heat source within a slender probe. These instruments are available commercially and have the advantages of rapidity and a small test specimen requirement. The probe is a useful research and development tool, but it has not been as accepted as the guarded hot plate, heat flow meter apparatus, or pipe insulation apparatus.

Thermal Conductance and Resistance

Thermal conductances (C-factors) and resistances (R-values) of many building assemblies can be calculated from the conductivities and dimensions of their components, as described in Chapter 27. Test values can also be determined experimentally by testing large, representative specimens in the hot box apparatus described in ASTM *Standards* C976 and C1363. This laboratory apparatus measures heat transfer through a specimen under controlled air temperature, air velocity, and radiation conditions. It is especially suited for large, nonhomogeneous specimens.

For in situ measurements, heat flux and temperature transducers are useful in measuring the dynamic or steady-state behavior of opaque building components (ASTM *Standard* C1046). A heat flux transducer is simply a differential thermopile within a core or substrate material. Two types of construction are used: (1) multiple thermocouple junctions wrapped around a core material, or (2) printed circuits with a uniform array of thermocouple junctions. The transducer is calibrated by determining its voltage output as a function of the heat flux through the transducer. For in situ measurements, the transducer is installed in either the wall or roof, or mounted on an exterior surface with tape or adhesive. Data obtained can be used to compute the thermal conductance or resistance of the building component (ASTM *Standard* C1155).

17. AIR CONTAMINANT MEASUREMENT

Three measures of particulate air contamination include the number, projected area, and mass of particles per unit volume of air (ASTM 2012). Each requires an appropriate sampling technique.

Licensed for single user. © 2021 ASHRAE, Inc.

Particles are counted by capturing them in impingers, impactors, membrane filters, or thermal or electrostatic precipitators. Counting may be done by microscope, using stage counts if the sample covers a broad range of sizes (Nagda and Rector 2001).

Electronic particle counters can give rapid data on particle size distribution and concentration. **Inertial particle counters** use acceleration to separate sampled particles into different sizes. Real-time **aerodynamic particle sizers (APS)** use inertial effects to separate particles by size, but instead of capturing the particles, they are sized optically (Cox and Miro 1997), and can provide continuous sampling; however, they tend to be very expensive. Other, less costly types of **optical particle counters (OPCs)** are also available, but they typically require careful calibration using the type of particle that is being measured for accurate results (Baron and Willeke 2001). Their accuracy also depends heavily on appropriate maintenance and proper application. Correction for particle losses (dropout in the sampling lines) during sampling can be particularly important for accurate concentration measurements. Concentration uncertainty (random measurement uncertainty) also depends on the number of particles sampled in a given sampling interval.

Particle counters have been used in indoor office environments as well as in cleanrooms, and in aircraft cabin air quality testing (Cox and Miro 1997).

Projected area determinations are usually made by sampling onto a filter paper and comparing the light transmitted or scattered by this filter to a standard filter. The staining ability of dusts depends on the projected area and refractive index per unit volume. For sampling, filters must collect the minimum-sized particle of interest, so membrane or glass fiber filters are recommended.

To determine particle mass, a measured quantity of air is drawn through filters, preferably of membrane or glass fiber, and the filter mass is compared to the mass before sampling. Electrostatic or thermal precipitators and various impactors have also been used. For further information, see ACGIH (2001), Lodge (1989), and Lundgren et al. (1979).

Chapter 46 of the 2019 *ASHRAE Handbook—HVAC Applications* presents information on measuring and monitoring gaseous contaminants. Relatively costly analytical equipment, which must be calibrated and operated carefully by experienced personnel, is needed. Numerous methods of sampling the contaminants, as well as the laboratory analysis techniques used after sampling, are specified. Some of the analytical methods are specific to a single pollutant; others can present a concentration spectrum for many compounds simultaneously.

18. COMBUSTION ANALYSIS

Two approaches are used to measure the thermal output or capacity of a boiler, furnace, or other fuel-burning device. The direct or **calorimetric test** measures change in enthalpy or heat content of the fluid, air, or water heated by the device, and multiplies this by the flow rate to arrive at the unit's capacity. The indirect test or **flue gas analysis** method determines heat losses in flue gases and the jacket and deducts them from the heat content (higher heating value) of measured fuel input to the appliance. A **heat balance** simultaneously applies both tests to the same device. The indirect test usually indicates the greater capacity, and the difference is credited to radiation from the casing or jacket and unaccounted-for losses.

With small equipment, the expense of the direct test is usually not justified, and the indirect test is used with an arbitrary radiation and unaccounted-for loss factor.

18.1 FLUE GAS ANALYSIS

Flue gases from burning fossil fuels generally contain carbon dioxide (CO_2) and water, with some small amounts of hydrogen (H_2), carbon monoxide (CO), nitrogen oxides (NO_x), sulfur oxides (SO_x), and unburned hydrocarbons. However, generally only concentrations of CO_2 (or O_2) and CO are measured to determine completeness of combustion and efficiency.

Nondispersive infrared (NDIR) analyzers are the most common laboratory instruments for measuring CO and CO_2. Their advantages include the following: (1) they are not very sensitive to flow rate, (2) no wet chemicals are required, (3) they have a relatively fast response, (4) measurements can be made over a wide range of concentrations, and (5) they are not sensitive to the presence of contaminants in ambient air.

In the laboratory, oxygen is generally measured with an instrument that uses O_2's paramagnetic properties. Paramagnetic instruments are generally used because of their excellent accuracy and because they can be made specific to the measurement of oxygen.

For field testing and burner adjustment, portable combustion testing equipment is available. These instruments generally measure O_2 and CO with electrochemical cells. The CO_2 is then calculated by an on-board microprocessor and, together with temperature, is used to calculate thermal efficiency.

19. DATA ACQUISITION AND RECORDING

Almost every type of transducer and sensor is available with the necessary interface system to make it computer compatible. The transducer itself begins to lose its identity when integrated into a system with features such as linearization, offset correction, self-calibration, and so forth. This has eliminated concern about the details of signal conditioning and amplification of basic transducer outputs, although engineering judgment is still required to review all data for validity, accuracy, and acceptability before making decisions based on the results. The personal computer is integrated into every aspect of data recording, including sophisticated graphics, acquisition and control, and analysis. Internet or intranet connections allow easy access to remote personal-computer-based data-recording systems from virtually any locale.

Direct output devices can be either multipurpose or specifically designed for a given sensor. Traditional chart recorders still provide a visual indication and a hard-copy record of the data, but their output is now rarely used to process data. These older mechanical stylus-type devices use ink, hot wire, pressure, or electrically sensitive paper to provide a continuous trace. They are useful up to a few hundred hertz. Thermal and ink recorders are confined to chart speeds of several centimetres per second for recording relatively slow processes. Simple indicators and readouts are used mostly to monitor the output of a sensor visually, and have usually been replaced by modern digital indicators. Industrial environments commonly use signal transmitters for control or computer data-handling systems to convert the signal output of the primary sensor into a compatible common signal span (e.g., the standard 4-20 mA current loop). All signal conditioning (ranging, zero suppression, reference-junction compensation) is provided at the transmitter. Thus, all recorders and controllers in the system can have an identical electrical span, with variations only in charts and scales offering the advantages of interchangeability and economy in equipment cost. Long signal transmission lines can be used, and receiving devices can be added to the loop without degrading performance. Newer instruments may be digitally bus based, which removes the degradation that may occur with analog signals. These digital instruments are usually immune to noise, based on the communications scheme that is used. They also may allow for self-configuration of the sensor in the field to the final data acquisition device.

The vast selection of available hardware, often confusing terminology, and challenge of optimizing the performance/cost ratio for

Licensed for single user. © 2021 ASHRAE, Inc.

a specific application make configuring a data acquisition system difficult. A system specifically configured to meet a particular measurement need can quickly become obsolete if it has inadequate flexibility. Memory size, recording speed, and signal processing capability are major considerations in determining the correct recording system. Thermal, mechanical, electromagnetic interference, portability, and meteorological factors also influence the selection.

Digital Recording

A digital data acquisition system must contain an interface, which is a system involving one or several analog-to-digital converters, and, in the case of multichannel inputs, circuitry for multiplexing. The interface may also provide excitation for transducers, calibration, and conversion of units. The digital data are arranged into one or several standard digital bus formats. Many data acquisition systems are designed to acquire data rapidly and store large records of data for later recording and analysis. Once the input signals have been digitized, the digital data are essentially immune to noise and can be transmitted over great distances.

The most popular physical layer bus standards used for data transmission are the TIA/EIA-485, IEEE 802.3, USB, IEEE 488, or general-purpose interface bus (GPIB) and the RS232 serial interface.

The **TIA/EIA-485 bus system** can be based on either two twisted pairs for full duplex (simultaneous signaling) operation or half duplex using only one twisted pair. A ground wire is generally required to provide a common reference ground for all the devices on the bus to eliminate common mode voltage problems caused by unequal ground potentials. The TIA/EIA-485 standard does not specify cabling length and data rate specifications, but refers to application guidelines (TSB-89). For practical applications, it gives an example of a specific manufacturer's 24AWG cable, for which the maximum distance between two devices is 1200 m at 100 kbps (TSB-89). The actual distance between devices for a given data rate depends on cable capacitance and impedance, network configuration, and grounding arrangements (TIA *Standards* TIA-485, TSB-89).

The **IEEE 802.3 bus standard** specifies both copper and optical fiber for physical linking of devices (IEEE *Standard* 802.3). The copper version uses either twin coaxial cables or four twisted-wire pairs with the twisted wire pairs being used more commonly. The twisted-wire pairs can support up to 10 Gbps with maximum distance of 100 m between devices depending on type of CAT (cable and telephone) cable used (IEEE 802.3). A 40 Gbps data rate specification over twisted pairs is expected to be released by end of 2016.

The **USB 2.0 and 3.1** uses one and three twisted pairs respectively for data transmission. Three additional wires are used for power, ground and shield in both USB 2.0 and USB 3.0. The USB 2.0 can provide 480 Mbps with a recommended length of 5 m based on the maximum 26 ns signal delay and cable specifications given in the USB 2.0 standard. The new USB 3.1 standard can support data transmission speeds of up to 10 Gbps with a recommended length of 3 m for a cable satisfying the standard's electrical requirements. Device distances can be increased by using either USB bridges/hubs or physical layer interfacing converters.

The **IEEE 488 bus system** feeds data down eight parallel wires, one data byte at a time. This parallel operation allows it to transfer data rapidly at up to 1 million characters per second. However, the IEEE 488 bus is limited to a cable length of 20 m and requires an interface connection on every meter for proper termination.

The **RS232 system** feeds data serially down two wires, one bit at a time. The distance between the devices is limited by maximum cable capacitance of 2500 pF at a maximum data rate of 20 kbps (TIA *Standard* TIA-232). This translates to typical distance of 15 m, which was the maximum length limit specified in an earlier version of the RS232 standard. For longer distances, it may feed a modem to send data over standard telephone lines.

These physical layer buses can be connected to a data acquisition unit or a personal computer directly or through a local area network (LAN) available in a facility for transmitting information. With appropriate interfacing, transducer data are available to any computer connected to the network.

Bus measurements can greatly simplify three basic applications: data gathering, automated limit testing, and computer-controlled processes. Data gathering collects readings over time. The most common applications include aging tests in quality control, temperature tests in quality assurance, and testing for intermittency in service. A controller can monitor any output indefinitely and then display the data directly on screen or record it on magnetic tape or disks for future use.

In automated limit testing, the computer compares each measurement with programmed limits. The controller converts readings to a good/bad readout. Automatic limit testing is highly cost-effective when working with large number of parameters of a particular unit under test.

In computer-controlled processes, the IEEE 488 bus system becomes a permanent part of a larger, completely automated system. For example, a large industrial process may require many electrical sensors that feed a central computer controlling many parts of the manufacturing process. An IEEE 488 bus controller collects readings from several sensors and saves the data until asked to dump an entire batch of readings to a larger central computer at one time. Used in this manner, the IEEE 488 bus controller serves as a slave of the central computer.

Dynamic range and accuracy must be considered in a digital recording system. **Dynamic range** refers to the ratio of the maximum input signal for which the system is useful to the noise floor of the system. The **accuracy** figure for a system is affected by the signal noise level, nonlinearity, temperature, time, crosstalk, and so forth. In selecting an 8-, 12-, or 16-bit analog-to-digital converter, the designer cannot assume that system accuracy is necessarily determined by the resolution of the encoders (i.e., 0.4%, 0.025%, and 0.0016%, respectively). If the sensor preceding the converter is limited to 1% full-scale accuracy, for example, no significant benefits are gained by using a 12-bit system over an 8-bit system and suppressing the least significant bit. However, a greater number of bits may be required to cover a larger dynamic range.

Data-Logging Devices

Data loggers digitally store electrical signals (analog or digital) to an internal memory storage component. The signal from connected sensors is typically stored to memory at timed intervals ranging from MHz to hourly sampling. Some data loggers store data based on an event (e.g., button push, contact closure). Many data loggers can perform linearization, scaling, or other signal conditioning and allow logged readings to be either instantaneous or averaged values. Most data loggers have built-in clocks that record the time and date together with transducer signal information. Data loggers range from single-channel input to 256 or more channels. Some are general-purpose devices that accept a multitude of analog and/or digital inputs, whereas others are more specialized to a specific measurement (e.g., a portable anemometer with built-in data-logging capability) or application (e.g., a temperature, relative humidity, CO_2, and CO monitor with data logging for IAQ applications). Stored data are generally downloaded using a serial interface with a temporary direct connection to a personal computer. Some data loggers allow downloading directly to a printer, or to an external hard drive or tape drive that can later be connected to a PC.

With the reduction in size of personal computers (laptops, notebooks, hand-held PCs, and palmtops), the computer itself is now being used as the data logger. These mobile computers may be left

Licensed for single user. © 2021 ASHRAE, Inc.

in the field, storing measurements from sensors directly interfaced into the computer. Depending on the particular application and number of sensors to be read, a computer card mounted directly into the PC may eliminate the external data acquisition device completely.

20. MECHANICAL POWER MEASUREMENT

Power measurement quantities mechanical power, and electrical power for both AC and DC loading (described in the section on Electric Measurement). Examples of mechanical power include shaft power and pumping power.

Measurement of Shaft Power

The measurement of shaft power associated with rotating machinery can be accomplished using a dynamometer setup which **independently** measures torque and rotation rate **(or angular velocity)**.

$$P = \omega T$$

where

P = power, W
ω = shaft angular velocity, rad/s
T = torque, N·m

Measurement of Fluid Pumping Power

Pumping power can be determined by independent measurements of volumetric flow rate and pressure differential across the pump.

$$P = \frac{Q(\Delta p)}{60}$$

where

P = power, W
Q = volumetric flow rate, L/min
Δp = pressure differential across the pump, kPa

20.1 SYMBOLS

A = flow area, m^2
a = thermocouple constant
C = correction factor
C_p = pitot-static probe pressure difference coefficient
c_p = specific heat at constant pressure, kJ/(kg·K)
D = distance; diameter
d = throat diameter
D_l = liquid diffusivity, m^2/s
$d\gamma/dx$ = moisture content gradient, m^{-1}
dp/dx = vapor pressure gradient, kPa/m
E = voltage
F_a = thermal expansion correction factor
H = height
J = mechanical equivalent of heat = 100 (N·m)/kJ
K = sensitivity (Figure 1); differential expansion coefficient for liquid in glass; constant (function of geometry and Reynolds number)
n = number of degrees that liquid column emerged from bath
p = absolute pressure, Pa
p_w = velocity pressure (pitot-tube manometer reading), Pa
P_{wet} = wetted perimeter
P = mechanical power, W
Q = discharge flow rate, m^3/s; L/min
R = resistance, Ω
r = (see Figure 9)
S = spot size
t = temperature, °C; wall thickness
$\bar{t}_r$ = mean radiant temperature, °C
T = torque, N·m
V = velocity, m/s; volume
W = width
w = mass flow rate, kg/s
w''_l = mass of liquid transferred through unit area per unit time, kg/(s·m^2)
w''_v = mass of vapor diffusing through unit area per unit time, mg/(s·m^2)
X = variable; velocity of stream, m/s

Greek

β = systematic (bias) error; ratio of diameters D_2/D_1 for venturi and sharp-edge orifice and d/D for flow nozzle
Δp = pressure differential across the pump, Pa
δ = deviation
ε = random error; emissivity (0.95 for black globe)
θ = tilt angle, °
θ_y = moisture content
μ = mean; vapor permeability, mg/(s·m·kPa)
ρ = density, kg/m^3
ρc = volumetric specific heat capacity
ω = shaft angular velocity, rev/s

Subscripts

1 = entering conditions; state 1
2 = throat conditions; state 2
a = air
b = bath
c = cross-sectional
e = equivalent of stream velocity
eff = effective
g = globe
h = hydraulic
i = pertaining to variable X
k = reading number
s = average of emergent liquid column of n degrees
true = true

CHAPTER 39

ABBREVIATIONS AND SYMBOLS

Abbreviations for Text, Drawings, and Computer Programs 38.1
Letter Symbols 38.1
Letter Symbols 38.4
Dimensionless Numbers 38.4
Mathematical Symbols 38.5
Piping System Identification 38.10
Codes and Standards 38.11

THIS chapter contains information about abbreviations and symbols for HVAC&R engineers.

Abbreviations are shortened forms of names and expressions used in text, drawings, and computer programs. This chapter discusses conventional English-language abbreviations that may be different in other languages. A **letter symbol** represents a quantity or a unit, not its name, and is independent of language. Because of this, use of a letter symbol is preferred over abbreviations for unit or quantity terms. Letter symbols necessary for individual chapters are defined in the chapters where they occur.

Abbreviations are never used for mathematical signs, such as the equality sign (=) or division sign (/), except in computer programming, where the abbreviation functions as a letter symbol. Mathematical operations are performed only with symbols. Abbreviations should be used only where necessary to save time and space; avoid their use in documents circulated in foreign countries.

Graphical symbols in this chapter of piping, ductwork, fittings, and in-line accessories can be used on scale drawings and diagrams.

Identifying piping by legend and color promotes greater safety and lessens the chance of error in emergencies. Piping identification is now required throughout the United States by the Occupational Safety and Health Administration (OSHA) for some industries and by many federal, state, and local codes.

1. ABBREVIATIONS FOR TEXT, DRAWINGS, AND COMPUTER PROGRAMS

Table 1 gives some abbreviations, as well as others commonly found on mechanical drawings and abbreviations (symbols) used in computer programming. Abbreviations specific to a single subject are defined in the chapters in which they appear. Additional abbreviations used on drawings can be found in the section on Graphical Symbols for Drawings.

Computer Programs

The abbreviations (symbols) used for computer programming for the HVAC&R industries have been developed by ASHRAE Technical Committee 1.5, Computer Applications. These symbols identify computer variables, subprograms, subroutines, and functions commonly applied in the industry. Using these symbols enhances comprehension of the program listings and provides a clearly defined nomenclature in applicable computer programs.

Some symbols have two or more options listed. The longest abbreviation is preferred and should be used if possible. However, it is sometimes necessary to shorten the symbol to further identify the variable. For instance, the area of a wall cannot be defined as WALLAREA because some computer languages restrict the number of letters in a variable name. Therefore, a shorter variable symbol is applied, and WALLAREA becomes WALLA or WAREA.

Most modern computer programming languages do not have the character limitations of older computer languages, but the limitations still exist in some older building automation controllers. It is good programming practice to include the complete name of each variable and to define any abbreviations in the comments section at the beginning of each module of code. Abbreviations should be used to help clarify the variables in an equation and not to obscure the readability of the code.

In Table 1, the same symbol is sometimes used for different terms. This liberty is taken because it is unlikely that the two terms would be used in the same program. If such were the case, one of the terms would require a suffix or prefix to differentiate it from the other.

2. LETTER SYMBOLS

Letter symbols include symbols for physical quantities (quantity symbols) and symbols for the units in which these quantities are measured (unit symbols). **Quantity symbols**, such as *I* for electric current, are listed in this chapter and are printed in italic type. A **unit symbol** is a letter or group of letters such as mm for millimetre or a special sign such as ° for degrees, and is printed in Roman type. Subscripts and superscripts are governed by the same principles. Letter symbols are restricted mainly to the English and Greek alphabets.

Quantity symbols may be used in mathematical expressions in any way consistent with good mathematical usage. The product of two quantities, a and b, is indicated by ab. The quotient is a/b, or ab^{-1}. To avoid misinterpretation, parentheses must be used if more than one slash (/) is used in an algebraic term; for example, $(a/b)/c$ or $a/(b/c)$ is correct, but not $a/b/c$.

Subscripts and superscripts, or several of them separated by commas, may be attached to a single basic letter (kernel), but not to other subscripts or superscripts. A symbol that has been modified by a superscript should be enclosed in parentheses before an exponent is added $(X_a)^3$. Symbols can also have alphanumeric marks such as ′ (prime), + (plus), and * (asterisk).

More detailed information on the general principles of letter symbol standardization are in standards listed at the end of this chapter. The letter symbols, in general, follow these standards, which are out of print:

Y10.3M	Letter Symbols for Mechanics and Time-Related Phenomena
Y10.4-82	Letter Symbols for Heat and Thermodynamics

Other symbols chosen by an author for a physical magnitude not appearing in any standard list should be ones that do not already have different meanings in the field of the text.

The preparation of this chapter is assigned to TC 1.6, Terminology.

Table 1 Abbreviations for Text, Drawings, and Computer Programs

Term	Text	Drawings	Program
above finished floor	—	AFF	—
absolute	abs	ABS	ABS
accumulat(e, -or)	acc	ACCUM	ACCUM
air condition(-ing, -ed)	—	AIR COND	—
air-conditioning unit(s)	—	ACU	ACU
air-handling unit	—	AHU	AHU
air horsepower	ahp	AHP	AHP
alteration	altrn	ALTRN	—
alternating current	ac	AC	AC
altitude	alt	ALT	ALT
ambient	amb	AMB	AMB
American National Standards Institute[1]	ANSI	ANSI	—
American wire gage	AWG	AWG	—
ampere (amp, amps)	amp	AMP	AMP, AMPS
angle	—	—	ANG
angle of incidence	—	—	ANGI
apparatus dew point	adp	ADP	ADP
approximate	approx.	APPROX	—
area	—	—	A
atmosphere	atm	ATM	—
average	avg	AVG	AVG
azimuth	az	AZ	AZ
azimuth, solar	—	—	SAZ
azimuth, wall	—	—	WAZ
barometer(-tric)	baro	BARO	—
bill of material	b/m	BOM	—
boiling point	bp	BP	BP
Brown & Sharpe wire gage	B&S	B&S	—
Celsius	°C	°C	°C
center to center	c to c	C TO C	—
circuit	ckt	CKT	CKT
clockwise	cw	CW	—
coefficient	coeff.	COEF	COEF
coefficient, valve flow	C_v	C_v	CV
coil	—	—	COIL
compressor	cprsr	CMPR	CMPR
condens(-er, -ing, -ation)	cond	COND	COND
conductance	—	—	C
conductivity	cndct	CNDCT	K
conductors, number of (3)	3/c	3/c	—
contact factor	—	—	CF
cooling load	clg load	CLG LOAD	CLOAD
counterclockwise	ccw	CCW	—
cubic centimetre	cm^3	CC	CC
cubic metre	m^3	CU M	CU M
decibel	dB	DB	DB
degree	deg. or °	DEG or °	DEG
density	dens	DENS	RHO
depth or deep	dp	DP	DPTH
dew-point temperature	dpt	DPT	DPT
diameter	dia.	DIA	DIA
diameter, inside	ID	ID	ID
diameter, outside	OD	OD	OD
difference or delta	diff., Δ	DIFF	D, DELTA
diffuse radiation	—		DFRAD
direct current	dc	DC	DC
direct radiation	dir radn	DIR RADN	DIRAD
dry	—		DRY
dry-bulb temperature	dbt	DBT	DB, DBT
effectiveness	—		EFT
effective temperature[2]	ET*	ET*	ET
efficiency	eff	EFF	EFF
efficiency, fin	—		FEFF
efficiency, surface	—		SEFF
electromotive force	emf	EMF	—
elevation	elev.	EL	ELEV
entering	entr	ENT	ENT
entering water temperature	EWT	EWT	EWT
entering air temperature	EAT	EAT	EAT
enthalpy	—	—	H
entropy	—	—	S
equivalent direct radiation	edr	EDR	—
evaporat(-e, -ing, -ed, -or)	evap	EVAP	EVAP
expansion	exp	EXP	XPAN
face area	fa	FA	FA
face to face	f to f	F to F	—
face velocity	fvel	FVEL	FV
factor, correction	—	—	CFAC, CFACT
factor, friction	—	—	FFACT, FF
fan	—	—	FAN
film coefficient,[3] inside	—	—	FI, HI
film coefficient,[3] outside	—	—	FO, HO
flow rate, air	—	—	QAR, QAIR
flow rate, fluid	—	—	QFL
flow rate, gas	—	—	QGA, QGAS
freezing point	fp	FP	FP
frequency	Hz	HZ	—
gage or gauge	ga	GA	GA, GAGE
gram	g	g	G
gravitational constant	G	G	G
greatest temp difference	GTD	GTD	GTD
heat	—	—	HT

Term	Text	Drawings	Program

[1]Abbreviations of most proper names use capital letters in both text and drawings.
[2]The asterisk (*) is used with ET*, effective temperature, as in Chapter 9 of this volume.
[3]These are surface heat transfer coefficients.
[4]Letter L also used for *Logarithm of* these temperature differences in computer programming.

3. LETTER SYMBOLS

Symbol	Description of Item	Typical Units
a	acoustic velocity	m/s
A	area	m^2
b	breadth or width	m
B	barometric pressure	kPa
c	concentration	kg/m^3
c	specific heat	kJ/(kg·K)
c_p	specific heat at constant pressure	kJ/(kg·K)
c_v	specific heat at constant volume	kJ/(kg·K)
C	coefficient	—
C	fluid capacity rate	W/K
C	thermal conductance	$W/(m^2·K)$
C_L	loss coefficient	—
C_P	coefficient of performance	—
d	prefix meaning differential	—
d or D	diameter	m
D_e or D_h	equivalent or hydraulic diameter	m
D_v	mass diffusivity	mm^2/s
e	base of natural logarithms	—
E	energy	kJ
E	electrical potential	V
f	film conductance (alternate for h)	$W/(m^2·K)$
f	frequency	Hz
f_D	friction factor, Darcy-Weisbach formulation	—
f_F	friction factor, Fanning formulation	—
F	force	N
F_{ij}	angle factor (radiation)	—
g	gravitational acceleration	m/s^2
G	mass velocity	$kg/(s·m^2)$
h	heat transfer coefficient	$W/(m^2·K)$
h	hydraulic head	m
h	specific enthalpy	kJ/kg
h_a	enthalpy of dry air	kJ/kg
h_D	mass transfer coefficient	m/s
h_s	enthalpy of moist air at saturation	kJ/kg
H	total enthalpy	kJ
I	electric current	A
k	thermal conductivity	W/(m·K)
k (or γ)	ratio of specific heats, c_p/c_v	—
K	proportionality constant	—
K_D	mass transfer coefficient	$kg/(h·m^2)$
l or L	length	m
L_p	sound pressure	dB
L_w	sound power	dB
m or M	mass	kg
M	molecular weight	kg/kg mol
n or N	number in general	—
N	rate of rotation	kPa
p or P	pressure	kPa
p_a	partial pressure of dry air	kPa
p_s	partial pressure of water vapor in moist air	kPa
p_w	vapor pressure of water in saturated moist air	kPa
P	power	kW
q	time rate of heat transfer	W
Q	total heat transfer	kJ
Q	volumetric flow rate	L/s
r	radius	m
r or R	thermal resistance	$(m^2·K)/W$
R	gas constant	J/(kg·K)
s	specific entropy	kJ/(kg·K)
S	total entropy	kJ/K
t	temperature	°C
Δt_m or ΔT_m	mean temperature difference	K
T	absolute temperature	K
u	specific internal energy	kJ/kg
U	total internal energy	kJ
U	overall heat transfer coefficient	$W/(m^2·K)$
v	specific volume	m^3/kg
V	total volume	m^3
V	linear velocity	
w	mass rate of flow	
W	weight	
W	humidity ratio of moist air (dry air basis)	g/kg
W	work	
W_s	humidity ratio of moist air at saturation (dry air basis)	g/kg
x	mole fraction	—
x	quality, mass fraction of vapor	—
x,y,z	lengths along principal coordinate axes	m
Z	figure of merit	—
α	absolute Seebeck coefficient	V/K
α	absorptivity, absorptance radiation	—
α	linear coefficient of thermal expansion	1/K
α	thermal diffusivity	
β	volume coefficient of thermal expansion	1/K
γ (or k)	ratio of specific heats, c_p/c_v	—
γ	specific weight	N/m^3
Δ	difference between values	—
ε	emissivity, emittance (radiation)	—
θ	time	s, h
η	efficiency or effectiveness	—
λ	wavelength	nm
μ	degree of saturation	—
μ	dynamic viscosity	mPa·s
ν	kinematic viscosity	m^2/s
ρ	density	kg/m^3
ρ	reflectivity, reflectance (radiation)	—
ρ	volume resistivity	Ω·m
σ	Stefan-Boltzmann constant	$W/(m^2·K^4)$
σ	surface tension	N/m
τ	stress	N/m^2
τ	time	s
τ	transmissivity, transmittance (radiation)	—
ϕ	relative humidity	—

4. DIMENSIONLESS NUMBERS

Fo	Fourier number	$\alpha\tau/L^2$
Gr	Grashof number	$L^3\rho^2\beta g(\Delta t)/\mu^2$
Gz	Graetz number	wc_p/kL
j_D	Colburn mass transfer	$Sh/ReSc^{1/3}$
j_H	Colburn heat transfer	$Nu/RePr^{1/3}$
Le	Lewis number	α/D_v
M	Mach number	V/a
Nu	Nusselt number	hD/k
Pe	Peclet number	GDc_p/k
Pr	Prandtl number	$c_p\mu/k$
Re	Reynolds number	$\rho VD/\mu$
Sc	Schmidt number	$\mu/\rho D_v$
Sh	Sherwood number	$h_D L/D_v$
St	Stanton number	h/Gc_p
Str	Strouhal number	fd/V

5. MATHEMATICAL SYMBOLS

Licensed for single user. © 2021 ASHRAE, Inc.

equal to	=
not equal to	≠
approximately equal to	≈
greater than	>
less than	<
greater than or equal to	≥
less than or equal to	≤
plus	+
minus	−
plus or minus	±
a multiplied by *b*	ab, $a \cdot b$, $a \times b$
a divided by *b*	$\frac{a}{b}$, a/b, ab^{-1}
ratio of circumference of a circle to its diameter	π
a raised to the power *n*	a^n
square root of *a*	$\sqrt{a}$, $a^{0.5}$
infinity	∞
percent	%
summation of	Σ
natural log	ln
logarithm to base 10	log

SUBSCRIPTS

These are to be affixed to the appropriate symbols. Several subscripts may be used together to denote combinations of various states, points, or paths. Often the subscript indicates that a particular property is to be kept constant in a process.

a,b,...	referring to different phases, states or physical conditions of a substance, or to different substances
a	air
a	ambient
b	barometric (pressure)
c	referring to critical state or critical value
c	convection
db	dry bulb
dp	dew point
e	base of natural logarithms
f	referring to saturated liquid
f	film
fg	referring to evaporation or condensation
F	friction
g	referring to saturated vapor
h	referring to change of phase in evaporation
H	water vapor
i	referring to saturated solid
i	internal
if	referring to change of phase in melting
ig	referring to change of phase in sublimation
k	kinetic
L	latent
m	mean value
M	molar basis
p	referring to constant pressure conditions or processes
p	potential
r	refrigerant
r	radiant or radiation
s	referring to moist air at saturation
s	sensible
s	referring to isentropic conditions or processes
s	static (pressure)
s	surface
t	total (pressure)
T	referring to isothermal conditions or processes
v	referring to constant volume conditions or processes
v	vapor
v	velocity (pressure)
w	wall
w	water
wb	wet bulb
0	referring to initial or standard states or conditions

These are to be affixed to the appropriate symbols. Several subscripts may be used together to denote combinations of various states, points, or paths. Often the subscript indicates that a particular property is to be kept constant in a process.

1,2,...	different points in a process, or different instants of time

GRAPHICAL SYMBOLS FOR DRAWINGS

Graphical symbols have been extracted from ANSI/ASHRAE *Standard* 134-2005. Additional symbols are from current practice and extracted from ASME *Standards* Y32.2.3 and Y32.2.4.

Piping

Heating

High-pressure steam	HPS
Medium-pressure steam	MPS
Low-pressure steam	LPS
High-pressure steam condensate	HPC
Medium-pressure steam condensate	MPC
Low-pressure steam condensate	LPC
Boiler blowdown	BBD
Pumped condensate	PC
Vacuum pump discharge	VPD
Makeup water	MU
Atmospheric vent	ATV
Fuel oil	FO(NAME)

Square-head cock
Unclassified (number and specify)

Fittings

The following fittings are shown without connection notations. This reflects current practice. The symbol for the body of a fitting is the same for all types of connections, unless otherwise specified. The types of connections are often specified for a range of pipe sizes, but are shown with the fitting symbol where required. For example, an elbow would be:

Steam turbine 

Steam turbine, condensing 

Electrical Equipment[a]

Symbols for electrical equipment shown on mechanical drawings are usually geometric figures with an appropriate name or abbreviation, with details described in the specifications. The following are some common examples.[b]

Motor control 

Disconnect switch, unfused 

Disconnect switch, fused 

Time clock 

Automatic filter panel 

Lighting panel 

Power panel 

[a] See ARI *Standard* 130 for preferred symbols of common electrical parts.
[b] Number each symbol if more than one; see ASME *Standard* Y32.4.

6. PIPING SYSTEM IDENTIFICATION

The material in piping systems is identified to promote greater safety and lessen the chances of error, confusion, or inaction in times of emergency. Primary identification should be by means of a lettered legend naming the material conveyed by the piping. In addition to, but not instead of, lettered identification, color can be used to identify the hazards or use of the material.

The data in this section have been extracted from ASME *Standard* A13.1.

Table 2 Examples of Legends

HOT WATER
AIR 700 kPA
H.P. RETURN
STEAM 700 kPA

Table 3 Classification of Hazardous Materials and Designation of Colors[a]

Classification	Color Field	Colors of Letters for Legend
Materials Inherently Hazardous		
Flammable or explosive	Yellow	Black
Chemically active or toxic	Yellow	Black
Extreme temperatures or pressures	Yellow	Black
Radioactive[b]	Purple	Yellow
Materials of Inherently Low Hazard		
Liquid or liquid admixture[c]	Green	Black
Gas or gaseous admixture	Blue	White
Fire-Quenching Materials		
Water, foam, CO_2, Halon, etc.	Red	White

[a] When preceding color scheme is used, colors should be as recommended in latest revision of NEMA *Standard* Z535.1.
[b] Previously specified radioactive markers using yellow or purple are acceptable if already installed and/or until existing supplies are depleted, subject to applicable federal regulations.
[c] Markers with black letters on green field are acceptable if already installed and/or until existing supplies are depleted.

Definitions

Piping Systems. Piping systems include pipes of any kind, fittings, valves, and pipe coverings. Supports, brackets, and other accessories are not included. Pipes are defined as conduits for the transport of gases, liquids, semiliquids, or fine particulate dust.

Materials Inherently Hazardous to Life and Property. There are four categories of hazardous materials:

- Flammable or explosive materials that are easily ignited, including materials known as fire producers or explosives
- Chemically active or toxic materials that are corrosive or are in themselves toxic or productive of poisonous gases
- Materials at extreme temperatures or pressures that, when released from the piping, cause a sudden outburst with the potential for inflicting injury or property damage by burns, impingement, or flashing to vapor state
- Radioactive materials that emit ionizing radiation

Materials of Inherently Low Hazard. These include all materials that are not hazardous by nature, and are near enough to ambient pressure and temperature that people working on systems carrying these materials run little risk through their release.

Fire-Quenching Materials. This classification includes sprinkler systems and other piped firefighting or fire protection equipment. This includes water (for firefighting), chemical foam, CO_2, Halon, and so forth.

Method of Identification

Legend. The legend is the primary and explicit identification of content. Positive identification of the content of the piping system is by lettered legend giving the name of the contents, in full or abbreviated form, as shown in Table 2. Arrows should be used to indicate the direction of flow. Use the legend to identify contents exactly and to provide temperature, pressure, and other details necessary to identify the hazard.

The legend should be brief, informative, pointed, and simple. Legends should be applied close to valves and adjacent to changes

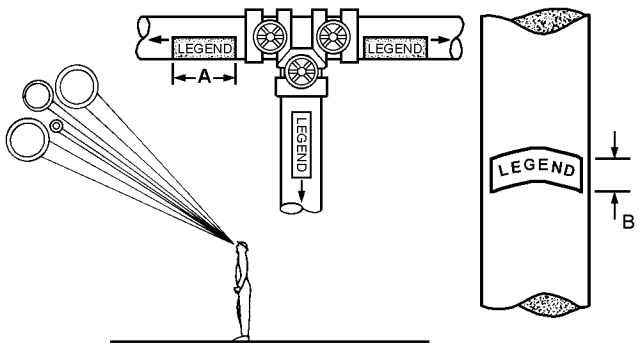

Fig. 1 Visibility of Pipe Markings

in direction, branches, and where pipes pass through walls or floors, and as frequently as needed along straight runs to provide clear and positive identification. Identification may be applied by stenciling, tape, or markers (see Figure 1). The number and location of identification markers on a particular piping system is based on judgment.**Color.** Colors listed in Table 3 are used to identify the characteristic properties of the contents. Color can be shown on or contiguous to the piping by any physical means, but it should be used in combination with a legend. Color can be used in continuous total length coverage or in intermittent displays.

Visibility. Pipe markings should be highly visible. If pipe lines are above the normal line of vision, the lettering is placed below the horizontal centerline of the pipe (Figure 1).

Type and Size of Letters. Provide the maximum contrast between color field and legend (Table 3). Table 4 shows the size of letters recommended. Use of standard size letters of 13 mm or larger is recommended. For identifying materials in pipes of less than 20 mm in diameter and for valve and fitting identification, use a permanently legible tag.

Table 4 Size of Legend Letters

Outside Diameter of Pipe or Covering, mm	Length of Color Field A, mm	Size of Letters B, mm
20 to 32	200	13
40 to 50	200	20
65 to 150	300	32
200 to 250	600	65
over 250	800	90

Unusual or Extreme Situations. When the piping layout occurs in or creates an area of limited accessibility or is extremely complex, other identification techniques may be required. Although a certain amount of imagination may be needed, the designer should always clearly identify the hazard and use the recommended color and legend guidelines.

7. CODES AND STANDARDS

ASHRAE. 2005. Graphic symbols for heating, ventilating, air-conditioning, and refrigeration systems. ANSI/ASHRAE *Standard* 134-2005.

ASME. 2007. Scheme for the identification of piping systems. ANSI/ASME *Standard* A13.1-2007. American Society of Mechanical Engineers, New York.

ASME. 1998. Graphic symbols for heating, ventilating and air conditioning. *Standard* Y32.2.4-1949 (RA 1988). American Society of Mechanical Engineers, New York.

IEEE. 2004. Standard letter symbols for units of measurement. *Standard* 260.1-2004. Institute of Electrical and Electronics Engineers, Piscataway, NJ.

IEEE. 1996. Letter symbols and abbreviations for quantities used in acoustics. *Standard* 260.4-1996. Institute of Electrical and Electronics Engineers, Piscataway, NJ.

yd^3	0.7646	m^3

To Obtain I-P	By	Divide SI

*Conversion factor is exact.

Notes: 1. Units are U.S. values unless noted otherwise.
2. Litre is a special name for the cubic decimetre. 1 L = 1 dm^3 and 1 mL = 1 cm^3.

The preparation of this chapter is assigned to TC 1.6, Terminology.

Rankine	x°R =	$x/1.8$	$(x - 491.67)/1.8$	x	$x - 459.67$	1°R =	5/9	5/9	1	1
Fahrenheit	x°F =	$(x + 459.67)/1.8$	$(x - 32)/1.8$	$x + 459.67$	x	1°F =	5/9	5/9	1	1

Notes: Conversions with * are exact.
The Btu and calorie are based on the International Table.
All temperature conversions and factors are exact.
The term centigrade is obsolete and should not be used.

When making conversions, remember that a converted value is no more precise than the original value. For many applications, rounding off the converted value to the same number of significant figures as those in the original value provides acceptable accuracy.

See ANSI *Standard* SI-10-1997 (available from ASTM or IEEE) for additional conversions.

CODES AND STANDARDS

THE codes and standards and other publications listed here represent practices, methods, or standard published by the organizations indicated. They are useful guides for the practicing engineer in determining test methods, ratings, performance requirements, and limits of HVAC&R equipment. Copies of these publications can be obtained from most of the organizations listed in the Publisher column, from Global Engineering Documents at **global.ihs.com**, or from Techstreet at **techstreet.com**. Addresses of the organizations are given at the end of the chapter. A comprehensive database with over 300,000 industry, government, and international standards is at **www.nssn.org**.

ASHRAE HANDBOOK

Additions and Corrections

The following presents additional information and technical errors found between June 15, 2018, and June 15, 2021, in the SI editions of the 2018, 2019, and 2020 *ASHRAE Handbook* volumes. Occasional typographical errors and nonstandard symbol labels will be corrected in future volumes. The most current list of Handbook additions and corrections is on the ASHRAE web site (www.ashrae.org).

The authors and editor encourage you to notify them if you find other technical errors. Please send corrections to: Handbook Editor, ASHRAE, 180 Technology Parkway, Peachtree Corners, GA, 30092, or e-mail hkennedy@ashrae.org.

2019 HVAC Applications

First page of Contributors. Charles Gulledge's employer should be listed as Environmental Air Systems, LLC.

p. 11.14, Fig. 13. Source year should be 2000, rather than 2007.

p. 19.2, Table 1. Source note should be "©ISO. This material is reproduced from ISO 14644-1:2015, with permission of the American National Standards Institute (ANSI) on behalf of the International Organization for Standardization. All rights reserved."

p. 61.3, Fig. 2. Bottom line of figure cut off. The figure in its entirety is as appears in the opposite column.

End papers. Title for Chapter 59 should be listed as "Indoor Airflow Modeling," and Chapter 60 should be "Integrated Project Delivery and Building Design."

2020 HVAC Systems and Equipment

Chapter 24, Tables 2 to 5. The data in these tables have been updated for greater accuracy. Replacement tables are provided on pages A.2 to A.4.

Consultant(s)
- None
- In-house security management
- Outside security consultant
- Government security (at time of design; confidential)
- Government security (at time of construction; highly confidential)

Risk Evaluation Status (see risk evaluation document for more detail)
- Baseline: No specialized operations, tenants may be relocated, long-term nonoccupancy presents minimal challenge
- Enhanced: Specialized or unique operations, larger facilities with high populations, long-term nonoccupancy undesirable
- Critical: Highly specialized or unique operations, high importance or visibility, long-term nonoccupancy unacceptable

Design Features: HVAC Security
- List Features

Design Features: Environmental Health and Safety
- List systems with enhanced air filtration and MERV rating
- List systems with enhanced safeties and alarms and types of devices used
- List zoning application
- List air intake minimum height above grade requirements
- List equipment to be located above exterior historical flood level data
- List systems to be on emergency power

Commissioning, Operation, Maintenance, and Recommissioning
- Commission beginning in design phase through construction phase
- Continuous commissioning in warranty phase
- Operation training and documentation beginning in design phase
- Preventive maintenance work order ready to implement in construction/commissioning phase
- Predictive maintenance features
- Mode of operation: evacuation, shelter-in-place, uninterrupted operation (list systems by one of these three categories)
- Recommissioning every (X) years by _____

Fig. 2 HVAC Security and Environmental Health and Safety Basis of Design Segment
(from 2019 Applications, p. 61.3)

Source: Oak Ridge National Laboratory, T. R. Sharp, calculated from U.S. DOE/EIA 2012 CBECS microdata.

** District chilled water use and cost are not reflected in building EUIs and cost metrics because they were not reported in the CBECS public database. Analysis showed there was potential this could significantly impact some EUIs for these building use types: college/university, dormitory/fraternity/sorority, entertainment/culture, library, hospital/inpatient health, and laboratory. Commentary in this chapter will explain the impact of chilled water systems on these categories.*

NOTE: Metrics will not exactly match those in CBECS Table PBA3 as shown on the CBECS website due to including propane and wood as energy sources and because EIA uses a database to generate Table PBA3 that is slightly different from the database they make available to the public.

Table 3 2012 Commercial Sector Floor Area and Source EUI Percentiles

	Calculated, Weighted			Calculated, Weighted Energy Use Index (EUI) Values					
				Source Energy, MJ/yr per gross square metre					
				Percentiles

COMPOSITE INDEX
ASHRAE HANDBOOK SERIES

This index covers the current Handbook series published by ASHRAE. The four volumes in the series are identified as follows:

R = 2018 Refrigeration
A = 2019 HVAC Applications
S = 2020 HVAC Systems and Equipment
F = 2021 Fundamentals

Alphabetization of the index is letter by letter; for example, **Heaters** precedes **Heat exchangers**, and **Floors** precedes **Floor slabs**.

The page reference for an index entry includes the book letter and the chapter number, which may be followed by a decimal point and the beginning page in the chapter. For example, the page number F30.6 means the information may be found in the 2021 HVAC Fundamentals volume, Chapter 30, beginning on page 6.

Each Handbook volume is revised and updated on a four-year cycle. Because technology and the interests of ASHRAE members change, some topics are not included in the current Handbook series but may be found in the earlier Handbook editions cited in the index.

Abbreviations, F38
Absorbents
liquid, F2.14; F32.3

Source: Oak Ridge National Laboratory, T. R. Sharp, calculated from U.S. DOE/EIA 2012 CBECS microdata.

** District chilled water use and cost are not reflected in building EUIs and cost metrics because they were not reported in the CBECS public database. Analysis showed there was potential this could significantly impact some EUIs for these building use types: college/university, dormitory/fraternity/sorority, entertainment/culture, library, hospital/inpatient health, and laboratory. Commentary in this chapter will explain the impact of chilled water systems on these categories.*
